INTRODUCTION

Roger Vickerman

In an increasingly globalized world, despite reductions in costs and time, transportation has become even more important as a facilitator of economic and human interaction; this is reflected in technical advances in transportation systems, increasing interest in how transportation interacts with society and the need to provide novel approaches to understand its impacts. This has become particularly acute with the impact that Covid-19 has had on transportation across the world, at local, national, and international levels. This Encyclopedia brings a cross-cutting and integrated approach to all aspects of transportation from work in many disciplinary fields, engineering, operations research, economics, geography, and sociology to understand the changes taking place.

Transportation is both influenced by, and an influencer of, changes in the economy and society. Increasing speeds have reduced journey times and made the world a smaller place as globalization has affected both where people live and work and from where they source their goods and materials. Increasing volumes of traffic, often on old and life-expired infrastructure, lead to congestion and delays. Constraints on public budgets have led to increasing pressure on the private sector to fund improvements requiring new and innovative financial solutions. While there are clear differences in the nature of the pressures felt in the developed and less developed economies, there is an increasing recognition that in all societies, there is an accessibility problem such that certain groups become disadvantaged by the lack of access to reliable and cost-effective transport. While the problems are clearly multidimensional, research on transportation is often constrained by single disciplinary approaches and this carries over into the practice of transport planning and policy. The Encyclopedia cuts across these artificial boundaries by taking an approach that emphasizes the interaction between the different aspects of research and aims to offer new solutions to understand these problems. Each of the nine sections is based around a familiar dimension of work on transportation, but brings together the views of experts from different disciplinary perspectives. Each section is edited by an expert in the relevant field who has sought chapters from a range of authors representing different disciplines, different parts of the world, and different social perspectives. In this way, the work is not just a reflection of the state of the art that serves as a starting point for researchers and practitioners, but also a pointer toward new approaches, new ways of thinking, and novel solutions to problems.

The nine sections are structured around the following themes: Transport Modes; Freight Transport and Logistics; Transport Safety and Security; Transport Economics; Traffic Management; Transport Modeling and Data Management; Transport Policy and Planning; Transport Psychology; Sustainability and Health Issues in Transportation. Some of the chapters provide a technical introduction to a topic while others provide a bridge between topics or a more future-oriented view of new research areas or challenges. While there is guidance to cross-referencing between chapters, readers are encouraged to explore the tables of contents of all the sections to get a full understanding of the issues. Much of the Encyclopedia was completed before the Covid-19 pandemic and clearly this will have changed the situation in many areas covered by this work; the advantage of this type of reference work is that relevant updates will be possible in future editions.

The Encyclopedia has only been possible because of the cooperation of a large number of people. Robert Noland, Georgina Santos, Xiaowen Fu, and Dick Ettema served as an Editorial Advisory Board identifying possible editors of sections and advising on the overall structure. The Section Editors, Edoardo Marcucci, Kevin Cullinane, Per Garder, Maria Börjesson, Edward Chung, Chandra Bhat, Maria Attard, and Carlo Prato,

carried out the work of identifying potential authors of individual chapters, commissioning these, encouraging authors and reviewing drafts. More than 600 authors and co-authors of chapters are, however, are ultimately responsible for the success of this venture. Thanks are also due to the key people at Elsevier, particularly the Publishers, Andre Wolff and Oliver Walter, and the Project Managers, Sophie Harrison and Natalie Bentahar; they have shown exemplary patience over more than 3 years in bringing this work to fruition.

LIST OF CONTRIBUTORS TO VOLUME 1

José Holguín-Veras

*Department of Civil and Environmental Engineering;
Center for Infrastructure, Transportation, and the
Environment; VREF Center of Excellence for Sustainable
Urban Freight Systems, Rensselaer Polytechnic Institute,
Troy, NY, United States*

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Introduction</i>	<i>vii</i>
<i>Contributors to Volume 1</i>	<i>ix</i>

VOLUME 1

Introduction to Transportation Economics	1
Market Failures and Public Decision Making in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	2
Demand for Freight Transport <i>José Holguín-Veras and Diana G. Ramírez-Ríos</i>	7
Cost Functions for Road Transport <i>José Manuel Vassallo</i>	13
Future of Urban Freight <i>Russell G. Thompson</i>	20
Operation Costs for Public Transport <i>Marco Batarce</i>	26
Natural Monopoly in Transport <i>André de Palma and Julien Monardo</i>	30
Freight Costs: Air and Sea <i>Yulai Wan and Dong Yang</i>	36
Transport Production and Cost Structure <i>Ricardo Giesen and Darío Farren</i>	46
The Concept of External Cost: Marginal versus Total Cost and Internalization <i>Sofia F. Franco</i>	56
Value of Time <i>John J. Bates</i>	67
Valuation of Carbon Emissions <i>Svante Mandell</i>	72
Valuation of Travel Time Variability Using Scheduling Models <i>Katrine Hjorth</i>	76

Value of Crowding <i>Daniel Hörcher</i>	84
What Drives Transport and Mobility Trends? The Chicken-and-Egg Problem <i>Nathalie Picard</i>	89
Pricing Principles in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	95
Long-Run Versus Short-Run Valuations <i>Stefanie Peer</i>	102
Value of Noise <i>Jon P. Nelson</i>	106
The Value of Life and Health <i>Henrik Andersson</i>	114
The Value of Security, Access Time, Waiting Time, and Transfers in Public Transport <i>Raquel Espino, Juan de Dios Ortúzar, and Luis I. Rizzi</i>	122
Demand for Passenger Transportation <i>Kenneth A Small and Robin Lindsey</i>	127
Real-World Experiences of Congestion Pricing <i>Charles Raux</i>	134
Distributional Effects of Congestion Charges and Fuel Taxes <i>Jonas Eliasson</i>	139
The Bottleneck Model <i>Dereje Abegaz and Yili Tang</i>	146
Dynamic Congestion Pricing and User Heterogeneity <i>Kathrin Goldmann and Gernot Sieg</i>	150
Economics of Parking <i>Daniel Albalade and Albert Gragera</i>	159
Loss Aversion and Size and Sign Effects in Value of Time Studies <i>Andrew Daly</i>	165
Intertemporal Variation of Valuations <i>James Fox</i>	170
The Rebound Effect for Car Transport <i>Bruno De Borger, Ismir Mulalic and Jan Rouwendal</i>	174
Elasticities for Travel Demand: Recent Evidence <i>Fay Dunkerley, Charlene Rohr and Mark Wardman</i>	179
Parking Price Elasticities <i>Stephan Lehner</i>	185
The Pareto Criterion and the Kaldor Hicks Criterion <i>Harald Minken</i>	190
Social Discount Rates <i>Lars Hultkrantz</i>	195
Cross-Elasticities between Modes <i>Mark Wardman and Jeremy Toner</i>	201
First-Best Congestion Pricing <i>Moez Kilani</i>	209

Ethical Aspects-Can We Value Life, Health, and Environment in Money Terms? <i>Jose M. Grisolia and Ken Willis</i>	216
Car tolls, Transit Subsidies for Commuting, and Distortions on the Labor Market <i>Ioannis Tikoudis¹ and Kurt Van Dender¹</i>	221
Demand Management and Capacity Planning of Airports <i>Stephen Ison and Lucy Budd</i>	227
Dealing With Negative Externalities: Low Emission Zones Versus Congestion Tolls <i>Valeria Bernardo, Xavier Fageda, and Ricardo Flores-Fillol</i>	231
The Rule-of-a-Half and Interpreting the Consumer Surplus as Accessibility <i>Mogens Fosgerau and Ninette Pilegaard</i>	237
Producer Surplus <i>Chau Man Fung</i>	242
The Robustness of Cost-Benefit Analyses <i>Morten Welde and James Odeck</i>	249
The GDP Effects of Transport Investments: The Macroeconomic Approach <i>James Laird and Daniel Johnson</i>	256
The Mohring Effect <i>Hugo E. Silva</i>	263
Public Transport Fare and Subsidy Optimization <i>Qianwen Guo and Zhongfei Li</i>	267
Transportation Equity <i>Rafael H. M. Pereira, and Alex Karner</i>	271
Impact of Transport Cost-Benefit Analysis on Public Decision-Making <i>Niek Mouter</i>	278
Causal Inference for Ex Post Evaluation of Transport Interventions <i>Daniel J. Graham</i>	283
Transport Cost and Location of Firms <i>Adelheid Holl</i>	291
Commuting, the Labor Market, and Wages <i>Jan Rouwendal, and Ismir Mulalic</i>	297
How to Buy Transport Infrastructure <i>Johan Nyström</i>	302
Procurement of Public Transport: Contractual Regimes <i>Andrew Smith, and Chris Nash</i>	308
The Mono-Centric City Model and Commuting Cost <i>Zhi-Chun Li, and Ya-Juan Chen</i>	315
Value of Time in Freight Transport <i>Gerard de Jong</i>	321
The Economics and Planning of Urban Freight Transport <i>Edoardo Marcucci, Valerio Gatta, and Michela Le Pira</i>	326
Incentives in Public Transport Contracts <i>Andreas Vigren</i>	332
Transportation Improvements and Property Prices <i>Alex Anas</i>	337

Transport Infrastructure Effects on Economic Output: The Microeconomic Approach <i>Patricia C. Melo</i>	347
Wider Economic Impacts of Transport Investments <i>Anthony J. Venables</i>	355
Employment Effects of Transport Infrastructure <i>Anna Matas, and Javier Asensio</i>	360
Regulatory Reforms and Competition in Public Transport <i>Didier van de Velde</i>	365
How to Finance Transport Infrastructure? <i>Tiziana D'Alfonso, and Giuseppe Catalano</i>	371
Congestion, Allocation and Competition on the Railway Tracks <i>John Armstrong, and John Preston</i>	378
Public Private Partnership <i>David Meunier, and Emile Quinet</i>	385
Airline Economics <i>Anming Zhang, Yahua Zhang, and Zhibin Huang</i>	392
Privatization and Deregulation of the Airline Industry <i>Achim I. Czerny, and Hao Lang</i>	397
Price Discrimination and Yield Management in the Airline Industry <i>Guoquan Zhang, Colin C.H. Law, Yahua Zhang, and Hangjun Yang</i>	404
Regulation and Competition in Railways <i>Chris Nash, and Andrew Smith</i>	409
Cycling Economics <i>Bert van Wee</i>	414
The Economic Rationale for High-Speed Rail <i>Ginés de Rus</i>	419
Rail Cost Functions <i>Kristofer Odolinski, and Phill Wheat</i>	425
Transport and International Trade <i>Siri Pettersen Strandenes</i>	431
Maritime Economics: Organizational Structures <i>Kevin P.B. Cullinane</i>	436
Port Planning and Investment <i>Jasmine Siu Lee Lam</i>	443
Estimating the Capital Stock of Transport Infrastructure <i>Heike Link</i>	449
The Economics of Reducing Carbon Emissions From Air and Road Transport <i>Olga Ivanova</i>	457
Regulation and Financing of Toll Roads <i>Marco Ponti</i>	464
Are Megaprojects too Transformational for Cost-Benefit Analysis? <i>Tom Worsley</i>	470
Economics of Transportation Safety <i>Ian Savage</i>	476

Cost Overruns of Transportation Infrastructure Projects <i>James Odeck, and Morten Welde</i>	483
The Downs-Thomson Paradox <i>Joel P. Franklin</i>	490
Policy Instruments for Plug-In Electric Vehicles: An Overview and Discussion <i>Jake Whitehead, Patrick Plötz, Patrick Jochem, Frances Sprei, and Elisabeth Dütschke</i>	496
Vertical and Horizontal Separation in the European Railway Sector and Its Effects on Productivity <i>Pedro Cantos-Sánchez</i>	503
How will Autonomous Vehicles Impact Car Ownership and Travel Behavior <i>Patrick M. Bösch, Felix Becker, Henrik Becker, and Kay W. Axhausen</i>	508
Policy Instruments to Reduce Carbon Emissions from Road Transport Computable General Equilibrium Analysis in Transportation Economics <i>Johannes Bröcker</i>	520
Estimation of Value of Time <i>Stefan Flügel, and Askill H. Halse</i>	527
The Taxation of Car Use in the Future <i>Griet De Ceuster, and Inge Mayeres</i>	534
Cost-Benefit Analysis and Other Assessment Techniques: Contrasts and Synergies <i>Paolo Beria</i>	540
Demand for Air Travel and Income Elasticity <i>Jing Lu, Yucan Meng, Changmin Jiang, and Cheng Lv</i>	547
Generalized Cost for Transport <i>Jepppe Rich</i>	555
The Impact of Electric Vehicles on Energy Systems <i>Patrick E.P. Jochem, Jake Whitehead, and Elisabeth Dütschke</i>	560
Uber versus Taxis <i>Georgina Santos</i>	566
Contract Efficiency in Public Transport Services <i>Philippe Gagnepain, and Marc Ivaldi</i>	572
Company Cars <i>Stefan Gössling</i>	580
Transportation Network Companies (TNCs) and the Future of Public Transportation <i>Susan Shaheen, and Adam Cohen</i>	584
Public Transport in Low Density Areas <i>Jani-Pekka Jokinen, Leif Sörensen, and Jan Schlüter</i>	589
Market Failures in Transport: Direct and Indirect Public Intervention <i>Federico Boffa, and Alberto Iozzi</i>	596
The Braess Paradox <i>Anna Nagurney, and Ladimer S. Nagurney</i>	601
VOLUME 2	
Introduction to Transportation Safety and Security <i>Per Gårder</i>	1

The Concept of “Acceptable Risk” Applied to Road Safety Risk Level <i>Claes Tingvall</i>	2
Crash Not Accident <i>Robert A. Scopatz</i>	6
Age and Gender as Factors in Road Safety <i>Marion Sinclair</i>	11
Aggressive Driving and Road Rage <i>James E.W. Roseborough, Christine M. Wickens, and David L. Wiesenthal</i>	17
Aircraft Maintenance and Inspection <i>Alan Hobbs</i>	25
Airport Security <i>Richard W. Bloom</i>	34
Transport Safety and Security: Alcohol <i>James C. Fell</i>	40
Animal Crashes <i>Michal Bil</i>	53
Attenuators <i>Simonetta Boria</i>	63
ATV, Snowmobile, and Terrain Vehicle Safety <i>David P. Gilkey, and William Brazile</i>	77
Automobile Safety Inspection <i>Subasish Das</i>	85
Aviation Safety: Commercial Airlines <i>Clarence C. Rodrigues</i>	90
Aviation Safety, Freight, and Dangerous Goods Transport by Air <i>Glenn S. Baxter and Graham Wild</i>	98
Bicycle Collision Avoidance Systems: Can Cyclist Safety be Improved with Intelligent Transport Systems? <i>Lars Leden</i>	108
Bicycle Infrastructure <i>Rock E. Miller</i>	115
Bicycles, E-Bikes and Micromobility, A Traffic Safety Overview <i>Höskuldur Kröyer</i>	125
Bicycles: The Safety of Shared Systems Versus Traditional Ownership <i>Mercedes Castro-Nuño and José I. Castillo-Manzano</i>	139
Bridge Safety <i>Per Erik Garder</i>	144
Carsharing Safety and Insurance <i>Elliot Martin and Susan Shaheen</i>	150
Carjacking <i>Terance D. Mieth, Christopher Forepaugh, Tanya Dudinskaya</i>	157
Collision Avoidance Systems, Airplanes <i>Ivan Ostroumov and Nataliia Kuzmenko</i>	164
Collision Avoidance Systems, Automobiles <i>Erick J. Rodríguez-Seda</i>	173

Connected Automated Vehicles: Technologies, Developments, and Trends <i>Azra Habibovic and Lei Chen</i>	180
Construction Zones <i>Jalil Kianfar</i>	189
Costs of Accidents <i>Ulf Persson</i>	196
Critical Issues for Large Truck Safety <i>Matthew C. Camden, Jeffrey S. Hickman, Richard J. Hanowski, and Martin Walker</i>	200
Demerit Points and Similar Sanction Programs <i>Matúš ťucha and Kristýna Josrová</i>	210
Driver State and Mental Workload <i>Dick de Waard and Nicole van Nes</i>	216
Drugs, Illicit, and Prescription <i>Rune Elvik</i>	221
Education, Training, and Licensing <i>Matúš ťucha and Kristýna Josrová</i>	228
Elderly Driver Safety Issues <i>Mark J King</i>	233
Emergency Response Systems <i>Frances L. Edwards</i>	240
Emergency Vehicles and Traffic Safety <i>Shamsunnahar Yasmin, Sabreena Anowar, and Richard Tay</i>	247
Encouragement: Awards and Incentives <i>Fred Wegman</i>	255
Enforcement and Fines <i>Matúš ťucha and Ralf Risser</i>	263
Epidemiology of Road Traffic Crashes <i>Sherrie-Anne Kaye, Judy Fleiter, and Md Mazharul Haque</i>	269
Evacuation Planning and Transportation Resilience <i>Karl Kim</i>	276
Exposure: A Critical Factor in Risk Analysis <i>Frank Gross, PhD, PE</i>	282
Passenger Ferry Vessels and Cruise Ships: Safety and Security <i>Wayne K. Talley</i>	290
Fuel Economy Standards: Impacts on Safety <i>Kenneth T. Gillingham and Stephanie M. Weber</i>	296
Hazardous Materials Transport <i>Dr. Arjan Vincent van der Vlies</i>	304
Head-on Crashes <i>John N. Ivan</i>	311
Helicopters in Emergency Medical Response <i>Stephen J.M. Sollid, M.D., PhD</i>	316
Horizontal and Vertical Geometry <i>Victoria Gitelman</i>	322

Human Factors in Transportation <i>Alison Smiley, Christina (Missy) Rudin-Brown</i>	331
In-Depth Crash Analysis and Accident Investigation <i>Yong Peng, Helai Huang, and Xinghua Wang</i>	346
Incident Detection Systems, Airplanes <i>Ivan Ostroumov and Nataliia Kuzmenko</i>	351
Inequality and Traffic Safety <i>Miles Tight</i>	358
Lighting <i>John D. Bullough</i>	361
Macroscopic Safety Analysis <i>Mohamed Abdel-Aty and Jaeyoung Lee</i>	367
Motor Vehicle Crash Reportability <i>John J. McDonough</i>	380
Nominal Safety <i>Per Erik Garder</i>	386
Parking Lots <i>Maxim A. Dulebenets</i>	392
Passenger Van Safety <i>Saksith Chalermpong and Apiwat Ratanawaraha</i>	401
Passive Prevention Systems in Automobile Safety <i>B. Serpil Acar</i>	406
Pedestrian Safety, Children <i>Mette Møller</i>	415
Pedestrian Safety, General <i>Muhammad Z. Shah, Mehdi Moeinaddini, and Mahdi Aghaabbasi</i>	420
Pedestrian Safety, Older People <i>Carlo Lui</i>	429
Visually Impaired Pedestrian Safety <i>Robert S. Wall Emerson</i>	435
Photo/Video Traffic Enforcement <i>Charles M. Farmer</i>	439
Powered Two- and Three-Wheeler Safety <i>Fangrong Chang, Helai Huang, and Md. Mazharul Haque</i>	443
Railroad Safety <i>Xiang Liu and Zhipeng Zhang</i>	451
Railroad Safety: Grade Crossings and Trespassing <i>Rahim F. Benekohal and Jacob Mathew</i>	466
Recreational Boating Safety: Usage, Risk Factors, and the Prevention of Injury and Death <i>Amy E. Peden, Stacey Willcox-Pidgeon, and Kyra Hamilton</i>	477
Refuge Islands <i>Christer Hydén</i>	487
Risk Perception and Risk Behavior in the Context of Transportation <i>Martina Raue and Eva Lerner</i>	494

Road Diets <i>Robert B. Noland</i>	500
Road Safety Audits <i>Xiao Qin</i>	508
Roadside Safety Barriers <i>Dean C. Alberson</i>	513
Road Safety Management in Selected Countries <i>Paul Boase and Brian Jonah</i>	519
Roadway Pavement Conditions and Various Summer and Winter Maintenance Strategies <i>Kamal Hossain, PhD P. Eng</i>	529
Safety of Roundabouts <i>Khaled Shaaban</i>	539
Rumble Strips, Continuous Shoulder, and Centerline <i>AnnaAnund and AnnaVadeby</i>	549
Safety Culture <i>Tor-Olav Nvestad</i>	554
Safety Data Quality Management <i>Robert A. Scopatz</i>	560
School Bus Safety <i>Yousif A. Abulhassan</i>	564
School Campus Traffic Circulation <i>Dimitrios Nalmpantis</i>	568
Sexual Violence in Public Transportation <i>Vania Ceccato</i>	576
Shared Space <i>Allison B. Duncan</i>	584
Side Area Safety and Side Slopes <i>José María Pardillo-Mayora</i>	593
Simulators <i>Nichole L. Morris, Curtis M. Craig, Jacob D. Achtemeier, and Peter A. Easterlund</i>	602
Sleep-Related Issues and Fatigue <i>Prof Marion Sinclair and Estelle Swart</i>	611
Speed Governors and Limiters <i>Christer Hydén</i>	617
Speed Limits on Rural Highways <i>Peter Tarmo Savolainen and Timothy Jordan Gates</i>	622
Speed Limits on Urban Streets <i>Anna Bray Sharpin, Claudia Adriazola-Steil, Ben Welle, and Natalia Lleras</i>	632
Speed-Reducing Measures <i>Vinod Vasudevan</i>	641
Striping, Signs, and Other Forms of Information <i>Kasem Choocharukul and Kerkritt Sriroongvikrai</i>	648
Suicides <i>Brendan Ryan</i>	656

Surrogate Measures of Safety <i>Nicolas Saunier and Aliaksei Laureshyn</i>	662
Targeting Transit: the Terrorist Threat and the Challenges to Security <i>Brian Michael Jenkins</i>	668
The Swedish Vision Zero: A Policy Innovation <i>Matts-Åke Belin</i>	675
Tire Safety <i>Saied Taheri</i>	681
Town Gates: Section on Transport Safety and Security <i>Charles Tijus</i>	685
Traffic Flow Volume and Safety <i>Athanasios Theofilatos and Apostolos Ziakopoulos</i>	692
Traffic Safety and Security of Taxis and Ride-Hailing Vehicles <i>Zhe Wang, Helai Huang, and Ye Li</i>	699

VOLUME 4

Introduction to Traffic Management <i>Edward C.S. Chung</i>	1
Urban Motorway Management <i>John Gaffney and Hendrik Zurlinden</i>	2
Ramp Metering Application <i>John Gaffney and Hendrik Zurlinden</i>	10
City Wide Coordinated Ramp Meters <i>John Gaffney and Hendrik Zurlinden</i>	21
Variable Speed Limits for Traffic Efficiency Improvement <i>José Ramón D. Frejo and Bart De Schutter</i>	33
Hard Shoulder Running <i>Justin Geistefeldt</i>	41
High-Occupancy Vehicle (HOV) and High-Occupancy Toll (HOT) Lanes <i>Roxana J. Javid, Jiani Xie, Lijiao Wang, Wenruifan Yang, Ramina Jahanbakhsh Javid, and Mahmoud Salari</i>	45
Reversible Lanes: Guidelines, Operation and Control, Research Directions <i>Gowri Asaithambi, Venkatesan Kanagaraj, and Madhuri Kashyap</i>	52
Electronic Toll Collection <i>Azusa Toriumi</i>	60
Road Pricing-Theory and Applications <i>Kian Keong Chin</i>	68
Road Pricing 1: The Theory of Congestion Pricing <i>Timothy D. Hau</i>	74
Road Pricing 2: Short- and Long-Run Equilibrium of Road Transportation <i>Timothy D. Hau</i>	83
Road Pricing 3: The Implications for Pricing Public Transportation <i>Timothy D. Hau</i>	90
Road Pricing 4: Case Study-The Implementation of Electronic Road Pricing in Hong Kong <i>Timothy D.</i>	103
Advanced Travelers Information Systems (ATIS) <i>Chintan Advani and Ashish Bhaskar</i>	106
Travel Time Reliability <i>Sharmili Banik, Anil Kumar, and Lelitha Vanajakshi</i>	109
Traffic Incident Management <i>Ruimin Li</i>	122
Traffic Incident Detection <i>Shuyan Chen and Yingjiu Pan</i>	128
Bottleneck <i>Kentaro Wada, Toru Seo, and Yasuhiro Shiomi</i>	134
Flow Breakdown <i>Kentaro Wada, Toru Seo, and Yasuhiro Shiomi</i>	143
Recurrent Congestion <i>Takahiro Tsubota</i>	154

Nonrecurrent Congestion <i>Takahiro Tsubota</i>	158
Freeway to Arterial Interfaces <i>Abolfazl Karimpour and Yao-Jan Wu</i>	162
Arterial Road Management <i>Jiaqi Ma, Yi Guo and Adekunle Adebisi</i>	169
Signalized Intersections <i>Chaitrali Shirke</i>	178
Protected Phase <i>Jiarong Yao, Yumin Cao, and Keshuang Tang</i>	185
Permitted Phase <i>Yumin Cao, Jiarong Yao, and Keshuang Tang</i>	196
Hook Turns: Implementation, Benefits, and Limitations <i>Sara Moridpour and Amir Falamarzi</i>	203
Traffic Signal Coordination <i>Rahim F. Benekohal</i>	213
Emergency Vehicle Priority (Preemption): Concept and Advancements <i>Chaitrali Shirke</i>	221
Signalized Roundabouts <i>Yetis Sazi Murat and Rui-jun Guo</i>	227
Turbo Roundabouts: Design, Capacity and Comparison With Alternative Types of Roundabouts <i>Marco Guerrieri and Raffaele Mauro</i>	238
Capacity of an Intersection <i>Ashish Verma and Milan Mathew Thomas</i>	247
Delay <i>Shinji Tanaka</i>	258
Queue Length <i>Shinji Tanaka</i>	263
Local Area Traffic Management <i>Michael A.P. Taylor</i>	268
On-Street Parking <i>Jun Chen and Guang Yang</i>	278
Off-Street Parking <i>Jun Chen and Guang Yang</i>	285
Parking Information Systems <i>Behrang Assemi and Douglas Baker</i>	289
Performance-Based Parking Management <i>Douglas Baker and Behrang Assemi</i>	299
Transit Priority <i>Wanjing Ma, Qiheng Lin, and Ling Wang</i>	307
Adaptive Bus Control <i>Monica Menendez</i>	315
Transit Fare Collection <i>Mahmoud Mesbah and Kamal Khanali</i>	325

Transit Information Systems <i>Ankit Kumar Yadav and Nagendra R Velaga</i>	331
Tram Lane Configurations and Driving Rules <i>Farhana Naznin</i>	338
Railway Crossing <i>Chunliang Wu and Inhi Kim</i>	341
Pedestrian Crossing (Crosswalk) <i>Miho Iryo-Asano, Wael K.M. Alhajyaseen, and Koji Suzuki</i>	346
Bike-Sharing System: Uncovering the “1Success Factors” <i>S.K. Jason Chang and Amanda Fernandes Ferreira</i>	355
Airspace Systems Technologies-Overview and Opportunities <i>Banavar Sridhar and Gano B. Chatterji</i>	363
Air Traffic Flow and Capacity Management <i>Li Weigang and Cristiano P Garcia</i>	380
Port Management <i>Maria G. Burns</i>	390
Port Performance Measurement from a Multistakeholder Perspective <i>Min-Ho Ha, Zaili Yang, and Young-Joon Seo</i>	396
Transport Modeling and Data Management <i>Chandra Bhat</i>	407
Computational Methods and Data Analytics <i>Bilal Farooq and David López</i>	408
Activity-Based Models <i>Renato Guadamuz and Rajesh Paleti</i>	414
Advanced Traveler Information Systems <i>Stephen D. Boyles</i>	418
Demand-Responsive Transit, Evaluation Studies <i>Sebastián Raveau</i>	423
Location Choice Models <i>Adam Wilkinson Davis</i>	428
Full Feedback and Equilibrium Modeling in Urban Travel Forecasting <i>Yu (Marco) Nie, Jun Xie, and David Boyce</i>	432
The Use and Value of Geographic Information Systems in Transportation Modeling <i>Ming Zhang</i>	440
Latent Demand and Induced Travel <i>Charisma F. Choudhury</i>	448
ICT, Virtual and In-Person Activity Participation, and Travel Choice Analysis <i>Jacek Pawlak and Giovanni Circella</i>	452
Public Transit Ridership Forecasting Models <i>Ipsita Banerjee, Deepa L, and Abdul Rawoof Pinjari</i>	459
Spatial Mismatch, Job Access, and Reverse Commuting <i>Gian-Claudia Sciarra</i>	468

Microsimulation and Agent-Based Models in Transportation <i>Milos Balac</i>	473
Choice Models in Transportation <i>Naveen Chandra Iraganaboina and Naveen Eluru</i>	477
Multi-Criteria Decision Analysis <i>Zhanmin Zhang and Srijith Balakrishnan</i>	485
The National Household Travel Survey Data Series (NPTS/NHTS) <i>Nancy McGuckin</i>	493
Route Choice and Network Modeling <i>Emma Frejinger and Maëlle Zimmermann</i>	496
Departure Time Choice Modeling <i>Khandker Nurul Habib</i>	504
Traveler Responses to Congestion <i>David T. Ory and Gayathri Shivaraman</i>	509
Origin-Destination Demand Estimation Models <i>William H.K. Lam, Hu Shao, Shuhan Cao, and Hai Yang</i>	515
Parking Demand Models <i>S.C. Wong, Zhi-Chun Li, and William H.K. Lam</i>	519
Pavement Management Systems <i>Senthilmurugan Thyagarajan</i>	524
Residential Location Choice Models <i>Shlomo Bekhor and Sigal Kaplan</i>	531
Transport Demand Management <i>Feiyang Zhang and Becky P.Y. Loo</i>	537
Traffic Flow Analysis <i>H. Michael Zhang and Jia Li</i>	544
Autonomous Vehicles and Transportation Modeling <i>Annesha Enam, Felipe de Souza, Omer Verbas, Monique Stinson, and Joshua Auld</i>	557
Ride-Hailing and Travel Demand Implications <i>Felipe F. Dias</i>	564
Transportation Modeling and Planning Software <i>Joel Freedman</i>	569
Transportation Statistics and Databases <i>Taha Hossein Rashidi</i>	574
Travel Surveys <i>Stacey G. Bricka</i>	587
Travel Demand Forecasting: Where Are We and What Are the Emerging Issues <i>Thomas F. Rossi</i>	590
Travel Model Calibration and Validation <i>Ram M. Pendyala</i>	596
Trip Chaining Analysis <i>Cynthia Chen and Yusak Susilo</i>	606
Vehicle Ownership Models <i>Dr. Sören Groth and Prof. Dr. Dirk Wittowsky</i>	612

Bicycle Sharing/Bikesharing <i>Catherine Morency and Jean-Simon Bourdeau</i>	617
Carsharing <i>Shiva Habibi and Frances Sprei</i>	623
Urban Recreational Travel <i>Long Cheng and Frank Witlox</i>	629
Place Perception and Travel Behavior <i>Kathleen Deutsch-Burgner and Konstadinos G. Goulias</i>	635

VOLUME 5

Transport Modes <i>Edoardo Marcucci</i>	1
Infrastructure Transport Investments, Economic Growth and Regional Convergence <i>Xavier Fageda and Cecilia Olivieri</i>	2
Transport Modes and an Aging Society <i>Charles B.A. Musselwhite and Theresa Scott</i>	6
Sustainable Mobility Paths <i>Erling Holden and Geoffrey Gilpin</i>	13
Vehicles that Drive Themselves: What to Expect with Autonomous Vehicles <i>Michele D. Simoni and Kara M. Kockelman</i>	19
Transport Modes and Tourism <i>Ila Maltese and Luca Zamparini</i>	26
Transport Modes and Accessibility <i>Bert van Wee</i>	32
Transport Modes and Globalization <i>Jean-Paul Rodrigue</i>	38
Transport Modes and Cities <i>Erick Guerra and Gilles Duranton</i>	45
Transport Modes and Remote Areas	51
Modeling Mode Choice in Freight Transport <i>Lóránt Tavasszy and Gerard de Jongb</i>	57
Travel Mode Choice as Reasoned Action <i>Sebastian Bamberg, Icek Ajzen, and Peter Schmidt</i>	63
Energy Consumption of Transport Modes <i>Zissis Samaras and Ilias Vouitsis</i>	71
Transport Modes and People With Limited Mobility <i>Roger L Mackett</i>	85
Transport Modes and Commuters <i>Colin G. Pooley</i>	92
Shopping and Transport Modes <i>Antonio Comi</i>	98
Transport Modes and Health <i>Jennifer S. Mindell and Sandra Mandic</i>	106

Multimodality in Transportation <i>Sören Groth and Tobias Kuhnimhof</i>	118
Transport Modes and Disasters <i>Brian Wolshon</i>	127
Big Data for Public Transport Planning <i>Jan-Dirk Schmöcker</i>	134
Active Transport: Heterogeneous Street Users Serving Movement and Place Functions <i>Regine Gerike, Stefan Hubrich, Caroline Koszowski, Bettina Schröter, and Rico Wittwer</i>	140
Electric Vehicles <i>Christine Eisenmann, Daniel Görges, and Thomas Franke</i>	147
Shared Mobility: An Overview of Definitions, Current Practices, and Its Relationship to Mobility on Demand and Mobility as a Service <i>Susan Shaheen, PhD and Adam Cohen</i>	155
Adoption of new travel information platforms <i>Sigal Kaplan</i>	160
ICT and Transport Modes <i>Galit Cohen-Blankshtain</i>	165
Mode Choice and Life Events <i>Joachim Scheiner</i>	171
Introduction to Air Transport <i>Milan Janić</i>	178
The History of Air Transportation <i>Richard P. Hallion</i>	192
The Geography of Air Transport <i>Lucy Budd and Stephen Ison</i>	198
The Future of Air Transport <i>Rico Merkert and James Bushell</i>	203
Air Transport and Its Territorial Implications <i>Lanfranco Senn</i>	208
Next Generation Travel: Young Adults' Travel Patterns <i>Tobias Kuhnimhof and Scott Le Vine</i>	215
Airport Network Planning and Its Integration with the HSR System <i>Francesca Pagliara, Juan Carlos Martín, and Concepción Román</i>	222
Airport Management <i>Peter Forsyth and Hans-Martin Niemeier</i>	229
Airport Regulation <i>Achim I. Czerny</i>	234
Air Route Planning and Development <i>Renan Peres de Oliveira and Gui Lohmann</i>	241
Airline Management <i>Sveinn Vidar Gudmundsson</i>	249
Air Cargo <i>Volodymyr Bilotkach</i>	258

Airline Regulation <i>Andrew R. Goetz</i>	263
Air Vehicles Classification <i>Vincenzo Torre</i>	269
Aircraft Manufacturing <i>Antonio Sollo</i>	290
A Geography of Road Transport in Cities <i>Cristian Domarchi and Juan de Dios Ortúzar</i>	300
The Future of Road Transport <i>Preston L. Schiller</i>	306
Road Transportation and Territorial Scale <i>Ana M. Condeço-Melhorado</i>	315
Road Modes: Walking <i>Kevin Manaugh, PhD Associate Professor</i>	320
Bus Public Transport Planning and Operations <i>Ehab Diab and Ahmed El-Geneidy</i>	326
Street Design for Active Travel <i>Bruce Appleyard</i>	333
Transit Planning and Management <i>Zakhary Mallett and Marlon G Boarnet</i>	349

Introduction to Transportation Economics

Maria Börjesson, VTI Swedish National Road and Transport Research Institute, Linköping University, Linköping, Sweden

A well-functioning transportation system is decisive for the modern society. High accessibility to workers, suppliers, jobs, services, and other activities is fundamental for all other sectors in the economy. It is also essential for the welfare of all citizens and their everyday lives. But the transport sector also generates negative external effects such as emissions, accidents, and noise. Moreover, huge public resources have for a long time been spent on infrastructure and transit provision. Still, the public resources allocated to the transportation system is dwarfed by the enormous resources of time and money spent on transportation by citizens and firms.

Moreover, in all countries, public decisions have a vast influence on the transportation system. Transport investments, maintenance, operations, pricing, regulations, and various policy measures have huge consequences for the economy and the welfare. Pricing instruments often under public control include vehicle and fuel taxes, transit fares, congestion charges, airport charges, waterway and port charges and railway track access charges. Public regulations and administrative policies, such as emission standards and safety regulations, also have a large impact on the transportation system.

The articles in this section span over a range of topics across the core of transportation economics: cost–benefit analysis methods; pricing and financing; industrial organization, procurement and contract analysis, as well as the interaction between the transportation system and the housing and labor markets. Some articles deal with cost–benefit analysis and wider impact of transport investments. Since transport investments and other public interventions in the sector generate both positive and negative effects, appraisal methods are essential in project and policy evaluation. Moreover, proposed mega-projects such as high-speed rail and metro extensions are often justified by their anticipated effects on regional economic growth, employment, land values, and opportunities for housing construction. Other articles cover issues of pricing, governance, regulations and institutional organization issues in the transportation sector. Such topics are receiving increasing attention, for several reasons. First, physical transport infrastructure is already well developed in many countries. Second, the resources allocated to transport infrastructure is reducing in many countries, and in other countries the prices of transportation infrastructure are increasing fast. At the same time crowding and congestion are increasing, calling for greater efficiency. Third, most of the future possibilities are not directly related to physical infrastructure: autonomous cars, a fossil-free transportation system, and real-time information to travelers. Electrification and digitalization might substantially impact the benefits of infrastructure investments. So in spite of the diversity of topics covered by the articles in this section, they are all interrelated in some way or another. Since economics is part of most domains of society, the articles are crosscutting themes with articles in other sections.

Market Failures and Public Decision Making in the Transport Sector

Introduction

In this chapter, we look into the motivation for public intervention in the transport sector. A market economy offers certain efficiency properties, but these can only be attained when a number of strong and unrealistic conditions is satisfied. When these conditions are not satisfied, markets may fail. These market failures are the main motivation for public intervention.

In [Section 1](#), we describe the main market failures in the transport sector, and we explain why they are a problem for efficiency. In [Section 2](#), we look at public decision making. We first consider the ideal policy intervention to resolve market failures. Then we introduce more realistic policy making institutions and discuss possible political failures.

Market Failures

To understand the concept of market failures it is instructive to start from a world without such failures, that is, an ideal world with perfectly functioning markets. In *The Wealth of Nations*, Adam Smith already argued that perfectly competitive markets would lead to highly desirable outcomes. They are nowadays typically summarized in the two theorems of welfare economics ([Johansson, 1991](#); [Salanié, 2000](#)).

The first theorem states that, when a set of basic assumptions are satisfied, a perfectly competitive equilibrium is Pareto-optimal. A Pareto optimum generates maximum efficiency, in the sense that it is impossible to improve the utility of one individual without decreasing the utility of other individuals. The second theorem shows that, assuming the government has perfect income redistribution instruments, any Pareto-optimal allocation can be achieved as a perfect competition equilibrium. This means that one can achieve an efficient equilibrium that is also equitable as a perfectly competitive equilibrium.

Although the world is far from this theoretical construct, a perfect equilibrium is a good benchmark: it allows to study the public policy questions associated with the different technical conditions that have to be satisfied (these include, among others, the absence of monopoly power, public goods and externalities, see below). When these conditions are not satisfied we say there are “market failures”: the operation of perfectly competitive markets is either impossible, or it generates inefficiencies. Market failures are of course not limited to the transport sector, they exist in many other sectors as well.

We focus on two assumptions that generate important market failures in the transport sector: increasing returns to scale (and, hence, market power) and external effects. In our discussion, we initially take the location of economic activity as given. Transport activities have also an important effect on the spatial distribution of economic activities, a topic we briefly discuss at the end of this section.

Increasing returns to scale implies that the average cost of production declines as more units are produced. Under those circumstances, it is cheaper to concentrate production in one firm or facility; splitting demand over multiple firms would only lead to higher average costs. In industries with increasing returns there will, therefore, be a limited number of producers. There, private firms no longer take market prices as given, but they understand they can exploit their market power. They can increase profit by producing less and selling at prices above the marginal production cost. This is inefficient: at the production level that is chosen, consumers’

willingness to pay (the market price) is still higher than the marginal cost, so that there remain untapped possibilities to increase the utility of consumers.

The supply of transport infrastructure is often characterized by increasing returns to scale. When one firm builds a road there is an important fixed cost, and the firm can add more lanes at a cost per lane which is approximately constant. The same holds for railway stations, railway lines, airports, ports, etc. The implication of returns to scale is that it is efficient to have only one supplier of capacity in a given region for each of these infrastructures. When this provider of infrastructure then sells access services to users of the infrastructure, he has a monopoly position. Simple profit maximization leads the provider to set prices above the marginal cost of capacity. When the price elasticity of demand by users of the infrastructure is low, prices will in fact be much higher than the marginal cost. The result is an insufficient supply of capacity: the economy as a whole could have benefited from a larger transport capacity.

Insufficient infrastructure capacity is not the only problem. When there is only one provider, there can be two other problems. The first is inappropriate selection of the quality offered by the producer. The motorway surface may or may not be smooth, it may be built for different speed levels, railway tracks may be more or less noisy, etc. The quality offered by a monopolist may be too high or too low, because his choice of quality is driven by profit maximization and not by a concern for overall welfare. A second problem is an insufficient level of innovation. Monopolists have low incentives to innovate. This has been demonstrated in the telecom sector, where the opening to competition has accelerated the innovation process despite the presence of increasing returns to scale in telecom networks.

Increasing returns are much less of a problem at the level of the operators of transport services. Consider the bus industry as an example, and interpret the number of bus trips offered as the relevant output variable. It is clear that the average cost per trip offered is approximately constant, as each trip requires a bus, some energy and a driver.

The transport sector generates important *external effects*. An external effect is present when the consumption or production activities of one economic agent decrease the utility of other agents without proper compensation. If agent A enjoys a particular consumption activity that is annoying for others, then she will consume too much of the activity and will not make efforts to reduce the negative effects imposed on others. If the number of agents is small (e.g., one agent imposes an externality on one other agent) then the externality problem can be resolved through negotiation and bilateral contracts (this is known as the [Coase conjecture](#)). However, in the case of transport externalities agents impose negative effects on many others, and each agent takes the actions of others as given.

We classify the negative external effects of the use of transport infrastructure in three groups: environmental externalities, congestion externalities, and accident externalities.

Car and bus traffic, aviation and shipping all use fossil fuels, emitting greenhouse gasses and generating *climate externalities*. The use of fossil fuels is also at the origin of other *environmental externalities* under the form of conventional air pollutants that are damaging health and ecosystems (particulates, nitrogen oxide, ozone). Some transport activities also create noise, departing airplanes or old motorcycles being the best examples. The consequence of a transport sector with important environmental externalities is that, compared to the ideal situation from a social perspective, transport volumes are too high, and not enough efforts are made to limit the damaging effects for the rest of society.

Congestion is another external effect. For example, when a road is intensively used, extra road users create delays for other users. Road use is often not directly priced, or it is priced uniformly over time via fuel excises; as a consequence, then there will be periods where a too high level of demand creates delays. Similarly, when an airport is intensively used, additional incoming flights cause delays for other passengers. When all flights are offered by a monopolist, his price will internalize *congestion* (because offering extra flights imposes delays on passengers of his other flights), but the price will be too high due to his monopoly power.

The equivalent of road congestion in public transport is the discomfort externality due to *crowding*. When public transport is supplied by a profit maximizing monopolist, one expects user prices to take account of these crowding externalities; they decrease the value and quality of his product, so the monopolist prefers to avoid this as it reduces his profit. However, the price will be higher than marginal social cost due to monopoly power. Of course, public transport is in practice not priced to maximize profit. Prices are often uniform and low (or de facto free for those who pay a fixed fee per month). Crowding can then be an important externality, as every user decreases the comfort of the other users of the same bus or train. Finally, note that there is also a positive externality associated

Table 1 Market failures in the transport sector

	Returns to scale	Environmental externalities	Congestion and crowding externalities	Accident externalities
Road infrastructure supply	De facto yes			
Road use		Climate, air pollution, noise	Delay for other cars	Debatable
Rail infrastructure	Yes, important			
Rail operation and use	Limited	Limited to noise	Discomfort for other passengers	Low
Bus supply				
Bus operation and use	Limited		Discomfort for other passengers	Low
Airports	Yes		Discomfort for other passengers	
Air transport use	Limited	Climate, air pollution, noise		
Ports	Yes			
Shipping	Limited	Climate		

with public transport. More passengers lead providers to increase frequency, and this reduces the average waiting time for passengers at bus and rail stops (this is known as the Mohring effect).

Often traffic *accidents* are also mentioned as an external effect of transport use. Accidents are more complex than the other externalities for three reasons. First, the effect on the average accident risk of adding an extra user is not necessarily positive. Second, users themselves suffer from potential accidents. Third, experience rating of insurance premiums may internalize an important part of the accident cost.

In [Table 1](#), we summarize the prevalence of increasing returns to scale and transport externalities for different transport services.

To conclude this section, note that the working of the transport sector is also important for the spatial equilibrium. Perfect competition has a hard time explaining differences in economic development across space. The presence of cities and interregional trade cannot be explained without resorting to increasing returns to scale and agglomeration externalities. Cities need commuting activities to function, and increasing returns to scale can only be fully exploited when transport costs are sufficiently low. Spatial inequality is at the origin of transport activities but, conversely, the strong decrease of freight and passenger transport costs has increased the concentration of economic activity. In this sense, changes in transport costs have long-term spatial externalities. Individual import and export decisions, as well as commuting and migration decisions, affect the location of economic activities; this in turn affects the utility of many other economic agents ([Proost and Thisse, 2019](#)). The analysis of these spatial externalities requires a more complex analysis that goes beyond the ambitions of this chapter.

Public Decision Making

There are different types of problems in public decision making. First, one has to find out what are the appropriate policies. Second, one has to make sure that politicians and the administration will select these policies. One cannot just assume that governments know the appropriate policies and implement them, so that welfare improves. There is no guarantee that this will be the case.

In this section, we first concentrate on the different types of policy instruments and briefly illustrate their advantages and disadvantages, touching also upon the information problems for the policy maker. Next, we discuss the problem of selecting good policies in a political system.

Choice of Policy Instruments by a Benevolent Planner

Most of the roads are supplied by the public sector although, in some cases, the need to finance the extension of roads has driven governments to turn to the private supply of roads. Road construction as well as pricing of road use is then *de facto* a private monopoly for that road. Neither the government nor the private sector has perfect information on the future use and revenues of the road, but the private sector may have an information advantage. There are two problems to be solved by the government. First, it has to make sure the roads have the right quality and are constructed by efficient firms. Second, prices for road use should be efficient. They should cover all marginal social costs, including the external costs of congestion and environmental damage, without additional profit margins beyond what is necessary to pay for the roads' construction. One solution would be to have an auction in which the quality of the road as well as user prices are specified. The firm that offers the highest value to the government is in principle the most efficient supplier. However, this solution is not without problems. It may suffer from the winner's curse (firms underestimating costs most have the highest probability of winning, implying the winning firm is likely to make losses and go bankrupt). Moreover, it is unclear how to adapt prices to new information.

For public transport supply, we distinguish infrastructure from operations. At the level of infrastructure, returns to scale are important so that supply by one monopolist is often optimal. The optimal supply and pricing of infrastructure for rail can be addressed using the same approach as for roads, combining auctions and restrictions on prices for the use of the infrastructure. For the supply of public transport operations (offering rail and bus services) on a given infrastructure, returns to scale are less important so that one can consider several suppliers. These will be competing for offering rail and bus services, or for airport slots. Allowing different operators to use the same rail tracks is now well accepted in most countries, but it is an important change compared to the times where the public transport infrastructure supply and operation was vertically integrated. The allocation of slots can again be done using auctions. Such auctions are, however, complex because operators have constraints that are ideally solved using combined auctions: an operator may attach a higher value to a combination of time slots that optimizes his timetable.

One distinguishes usually three types of policy instruments to address *externalities* associated to the use of a transport good: prices, tradeable permits, and regulations. The instruments can also be used in combination.

The optimal policy toward an externality has three properties. Take the example of a polluting car. First, the cost of making the car greener should be equal to the marginal benefit of reducing the environmental damages of the use of the car. Second, the user cost of a car trip (where the car has the optimal level of "greenness") should include the remaining pollution damage cost). Third, the policy should contain incentives for technological progress. The optimal environmental policy is always a combination of reducing the polluting activity, making the activity cleaner and stimulating better technologies. To reach this optimum the policy should focus as directly as possible on the externality itself.

Consider how different instruments address environmental and congestion externalities. Bear in mind that the cost of making an activity cleaner is better known by the polluters than by the policy maker.

The main environmental externalities are associated to road use, aviation, and shipping. *Climate externalities* can be addressed via excise taxes that are proportional to the carbon content of the fuel. This policy instrument can also guarantee cost efficiency across different sectors of the economy, as the origin of the carbon emissions does not matter for the damage. Therefore, the same tax on carbon should prevail in all sectors of the economy. The second type of instrument that can be used are tradable emission permits for carbon. In this case, the total quantity of emissions in the transport sector is fixed, the rights are distributed or auctioned, and a market for the trade of permits makes sure the marginal cost of emission reduction is identical across sectors. Except for the transaction costs, this instrument is as efficient as the tax instrument if the total emission reduction achieved is the same. Note that, in the case of taxes or tradable permits, the policy maker does not have to know the costs of emission reduction of the different polluters. As long as the tax or permit price is the same for all polluters, the emission reduction is organized in a cost efficient way thanks to the working of the price mechanism. The tax and permit price is also a stimulus for technological progress as long as there is a long-term commitment to keep the emission tax or permit price high enough. The third instrument is a standard on emissions; this typically takes the case of a fuel efficiency standard. However, the government lacks the information on the costs of emission reduction, so that a standard on emissions is less cost-effective to reduce emissions. Even when the fuel efficiency standard in a subsector like cars is tradable among manufacturers, it is still less efficient because the diversity in the use of vehicles is not taken into account.

Besides these three basic instruments, many other policy instruments to tackle climate change are possible (and are used): subsidies for low emission vehicles or modes, land-use policies, etc. Such instruments are generally less efficient: they do not offer the right balance between making the transport activity greener and reducing the transport activity in function of the remaining emissions.

Other pollutants can be addressed using the same instruments. The main difference is that their damage is more localized, so that damage increases with population density. Spatial differentiation of the stringency of policies is therefore needed, but this is difficult to achieve. Moreover, the emissions of conventional air pollutants are more difficult to measure. This is the reason why governments turn to second-best policies like emission standards or low emission zones, where only certain types of vehicles are allowed to operate.

External *congestion* costs require congestion fees that are differentiated across space and time. These tax or toll instruments serve to make road users pay for the additional delays they cause to other users. An alternative policy is to use tradable driving rights that are differentiated over space and time. Whenever they achieve the same allocation of traffic as the optimal congestion tax—and in the absence of uncertainty—the driving rights are as efficient as the congestion tax. Other known policies to address congestion are much less efficient, including adding road capacity, subsidizing public transport, etc.

Problems of implementation and acceptance imply that most policy instruments to address externalities are nonprice measures that largely escaped the attention of transport economists: speed bumps, speed restrictions, pedestrian zones, etc.

Choice of Policy Instruments by the Political Process

There is as yet no general theory of the political process. Political scientists and economists developed simplified models that give useful insights for specific problems, but the political process can itself be very complex.

It is commonly believed that market failures always justify government intervention. However, the decision-making process itself and the distinction between the legislative and executive branches of government imply a number of potential inefficiencies. These are referred to as political failures. We provide in this section a few illustrations of political failures based on an simplified model.

Take the case of a country with two homogeneous groups of citizens. There are λN citizens of type A and $(1 - \lambda)$ citizens of type B. Consider a transport project (road or public transport) that costs C and benefits only citizens of type A. Group A could be car users having each a benefit b of using the new road, while group B could be citizens without a car. Alternatively, A and B could represent citizens of two regions or cities in a federation. We further assume the project is paid by a uniform lump-sum tax. So every citizen pays C/N .

The project is justified in cost–benefit terms when total benefits are larger than total costs, so when

$$\lambda N \cdot b > C \quad \text{or} \quad b > C/\lambda N.$$

Consider now first simple *majority voting* to make decisions. We immediately note two potential types of political failures. First, when group A has the majority, it may accept the project even when the project is socially undesirable. This group will decide to accept the project if the benefit b for each of its citizens satisfies $b > C/N$. If the project is such that $C/N < b < C/\lambda N$, group A will accept an inefficient project. This occurs because group A benefits but the costs of the projects are spread over the whole population. Second, when group A has no majority, it will never get a good project accepted, because the citizens of group B will not agree to pay for projects that do not benefit them. The voting process is capable of accepting some of the good projects (those having large benefits for the majority) and stopping some of the bad projects (those having very low net benefits for the majority and for the minority), but the process is not very selective. Some good projects will be rejected, some bad projects will be accepted. The reason is twofold: the intensity of benefits is not measured, and the minority is discriminated against. Note that lobbying and rent-seeking behavior may cause further inefficiencies in decision making.

Many political decisions are taken in a *representative democracy* system. Each of the regions has one representative and they decide on the allocation of projects. One possible equilibrium has an agenda setter that forms a minimum winning coalition of

representatives of regions that have low cost projects so that he can select a large project for his region without losing the majority. This set up has been used to explain the allocation of federal highway funds over the different states in the US. It was found that the allocation of funds was highly inefficient: for each dollar spend on highways, there was a dollar wasted.

When public funds have to be allocated over different regions and there are spillovers between regions, one needs additional restrictions on the decision process. When constitutional restrictions can be built into the pricing and investment of transport infrastructure, the outcomes can be relatively efficient. One such restriction could be that pricing should be uniform across regions.

Introduce now *politicians* in the decision process. Decisions are taken by a majority but they are executed by professional politicians and agencies. Consider again one project benefitting citizens in A only. However, assume that the quality of the politician matters: a good politician can realize the project for a cost lower than a bad politician: $C_L < C_H$. The bad politician may be lazy or may be more interested in capturing personal benefits rather than exerting effort for the public project. Assume furthermore that the project will only pass the cost-benefit criterion when a good politician is chosen. But selecting a good politician is difficult as good and bad politicians are indistinguishable *ex ante*. Often one needs to observe them for at least one period before knowing the politician's quality. Moreover, suppose a bad politician can pretend to be a good one in the first period; they have incentives to do so because they know they can get some personal rents doing a poor job in the second period. This then gives yet another example of a political failure: a good project selected in the first period may be ruined by the bad politician in the second period.

Conclusion

Transport activities suffer from important market failures, including increasing returns that lead to market power, and a series of external costs, including climate change, pollution, congestion, and accident risks. We reviewed the socially optimal policy instruments (pricing, regulation, use of permits) needed to cope with these market failures. Moreover, we discussed the possible political failures policy makers encounter when trying to implement desirable transport policies in a democratic system. Despite problems of possible political failures due to the voting process, due to lobbying, due to common pool financing and due to bad politicians, the democratic political process is still often qualified as the most desirable (the least bad) selection process. It allows to select some really good projects and avoid some really bad projects, and it may help in selecting good politicians.

Introduction

The demand for freight supplies is a physical expression of the economy, which is an obvious consequence of the fact that large portions of economic transactions entail the exchange of money for physical supplies. In this context, by transporting the supplies from points of production to points of consumption, supply chains close the loop in economic exchanges, and enable households and businesses to use the supplies in the manner desired. Since the vast majority of human or economic activities need supplies of one form or another, supply chains are pervasive. At the root of this process, one finds the demand for supplies at the receiving locations.

To gain insight into freight demand, it is important to understand the role of supply chains. Modern supply chains tie together multiple production and consumption stages that typically start with raw or recycled input materials, and end with the shipment of products for final consumption (Holguín-Veras et al., 2017). In all cases, an agent produces and/or sends supplies (the shipper) that are then consumed by a different agent (the receiver), after they are transported by the carrier. At each one of these stages supplies are consumed, transformed, produced, or stored. In modern times, with the surge of e-commerce, individuals and households have become integral parts of business-to-consumer supply chains. Compounding the inherent challenges, the logistics industry must now ensure efficient flows of supplies to both commercial establishments and households. Notwithstanding their importance, data about freight demand are very hard to get, as there are only a handful of publicly available estimates.

This paper attempts to fill this void by describing empirical evidence concerning freight demand. To do so, the authors gathered data and results from several sources representing developed and developing countries, different levels of geography (i.e., multi-national, national, and metropolitan), and a time span from the 1960s to current times. The data collected were post-processed to estimate the per-capita freight generation (FG), that is, the total amount of freight transported by type of commodity, divided by the corresponding population. The resulting values were analyzed to identify similarities and differences.

This paper has four sections in addition to this introduction. Section “Urban Economies” provides a brief overview of urban economies and their composition in terms of industry sectors. Section “Freight Generation” discusses the concepts of FG and freight trip generation (FTG). Section “Empirical Estimates” analyzes the empirical estimates of FG for the different cases considered in this paper. Section “Conclusion” summarizes the chief insights of this paper.

Urban Economies

The most straightforward way to illustrate the importance of freight activity and supply chains is to identify the sectors of the economy that, directly or indirectly, depend on supply chains to perform their activities. To this effect, one can create two major clusters of industry sectors. The first, freight-intensive sectors (FIS), corresponds to the industry sectors for which the production and consumption of freight is an indispensable component of their economic activities. The second cluster, service-intensive sectors (SIS), represents those sectors where the provision of services is the primary activity and the production or consumption of freight supplies is of secondary importance. It should be noted that both FIS and SIS produce and consume supplies, though the amounts generated by SIS are smaller than those generated by FIS. The industry sectors, defined using the North America Industry Classification System (NAICS), included in FIS and SIS are as follows:

- Freight-intensive sectors (FIS)
 - NAICS 11: Agriculture, forestry, fishing, and hunting
 - NAICS 21: Mining, quarrying, oil/gas, etc.
 - NAICS 22: Utilities
 - NAICS 23: Construction

- NAICS 31-33: Manufacturing
- NAICS 42: Wholesale trade
- NAICS 44-45: Retail trade
- NAICS 48-49: Transportation and warehousing
- NAICS 72: Accommodation and food services
- Service-intensive sectors (SIS):
 - NAICS 51: Information
 - NAICS 52: Finance and insurance
 - NAICS 53: Real estate and rental and leasing
 - NAICS 54: Professional, scientific, and technical services
 - NAICS 55: Management of companies
 - NAICS 56: Administrative, support, waste management, etc.
 - NAICS 61: Educational services
 - NAICS 62: Healthcare and social assistance
 - NAICS 71: Arts, entertainment, and recreation
 - NAICS 81: Other services
 - NAICS 92: Public administration

To illustrate the relative importance of FIS and SIS, the authors analyzed establishment and employment data by industry sector for all of the metro/micropolitan areas—defined by the US Census Bureau as “a core area containing a substantial population nucleus, together with adjacent communities having a high degree of economic and social integration with that core” (US Census Bureau, 2017)—in the United States (US Census Bureau, 2013a). Metropolitan areas are those with more than 50,000 people, while micropolitan areas have between 10,000 and 49,999 people (US Census Bureau, 2013b). The totals by industry sector are shown in **Table 1** and **Table 2** (Holguin-Veras and Aros-Vera, 2016). The results show that FIS capture 44.7% of commercial establishments (**Table 1**), and 49.4% of the employment in the United States; the rest corresponds to SIS (**Table 2**). It is worth noting that transportation and warehousing accounts for only 2.8% of the establishments and 3.6% of employment (these numbers likely underestimate the activity, as they do not include private fleets). These numbers imply that the performance of the transportation

and warehousing sector—a relatively small portion of the employment and establishments in the country—directly impacts about half the US economy, and indirectly impacts the other half. In developing economies, where the service economy is less developed, the impacts of the transportation and warehouse sector on the overall economy are even larger, because of the larger role played by the FIS. In Bangladesh, for instance, the authors estimate that the share of FIS employment is about 70% (Holguín-Veras et al., 2018).

Freight Generation

The production and consumption of cargo, or FG, should not be confused with the production and consumption of vehicle trips, or FTG. FG is an expression of the economic activity performed at businesses, by which input materials are consumed, transformed, or stored. FTG, in contrast, is the result of the logistic decisions concerning how best to transport the FG in terms of shipment size, frequency of deliveries, and vehicle/mode used (Holguín-Veras et al., 2017).

FG refers to the amount of cargo produced and consumed in the study area at the establishment or zonal level. Freight production (FP) represents the amount produced, while freight attraction (FA) is the amount of freight consumed. FG is the sum of both FA and FP. FTG is less straightforward, as it is the result of the joint decision of shipment size and frequency, which enables large business establishments to receive larger shipments, minimally increasing the amount of vehicle trips produced (Holguín-Veras et al., 2014).

Distinguishing FG from FTG makes it easier to identify what should be the primary focus of freight policy. From the economic point of view, the production and consumption of supplies are beneficial activities that help satisfy the needs of consumers and businesses. At the same time, the freight traffic that these activities generate is associated with large amounts of negative externalities—pollution, congestion, and accidents—that ought to be mitigated or eliminated altogether (Ogden, 1977). The chief objective of freight policy should be to ensure that the flows of supplies are as efficient as possible, and that the resulting freight traffic produces as little negative externalities as practically and economically possible.

Gaining insight into FG patterns is important as they provide a revealing snapshot of the corresponding economy. Given the well-known interconnections between the economy and freight activity, the amount of cargo generated within a region (the FG) provides insights into the region's economy. To facilitate comparison of results, without having to account for the difference in geographical scales and income, the authors computed a per-capita FG, which was obtained as the total amount of freight transported in a typical day divided by the corresponding population, and is expressed as kg/person per day. This simple metric provides an intuitive understanding of the amount of freight handled within a given jurisdiction that reflects the effect of income.

Empirical Estimates

This section presents estimates of per-capita FGs for different countries, geographic scales, and time periods. The source materials represent three different levels of geography, six different countries (both developed and developing), and different survey methodologies. These sources correspond to:

- Multinational: The 28 countries of the European Union (EU-28) (Eurostat, 2017)
- National: United States (US Census Bureau, 2018), China (China Transportation Department, 2013; China National Bureau of Statistics, 2018), Sweden (Transport Analysis, 2019), Colombia (Banco Interamericano de Desarrollo, 2013), Bangladesh (Holguín-Veras et al., 2018), and the Dominican Republic (Holguín-Veras, 1984)
- Metropolitan: The tri-state area (i.e., New York, New Jersey, and Connecticut) (Wood, 1970) and Medellín (Colombia) (Gonzalez-Calderon et al., 2018)

To ensure comparability of results, the original estimates were reclassified using the Standard Classification of Transported Goods (SCTG) (Bureau of Transportation Statistics, 2017). However, doing so was not straightforward, as the sources analyzed here adopted different definitions of commodity types that do not always line up well with the SCTG. Thus, the reclassification was far from perfect. Another source of discrepancies is the differences in scope of the studies; in some cases, such as the United States and EU, all modes were considered, while in other studies—Bangladesh, Colombia, and the Dominican Republic—only the highway modes were accounted for. In the latter case, for instance, the flows of coal and oil transported by water modes and pipelines, without using highways at all. Thus, the values of per-capita FGs presented here should be interpreted as order-of-magnitude estimates. The results are shown in Table 3. To facilitate referencing, the authors adopted the nicknames underlined in Table 3 to refer to specific SCTGs.

Table 3 also shows the ways in which the data were collected. “Mixed surveys” indicates that the data were obtained by means of surveys that targeted multiple agents (e.g., carriers, shippers, or receivers). “Surveys + models” refers to the technique developed by the authors and colleagues, successfully pilot-tested by Holguín-Veras et al. (2018). The most unique aspect of this approach is that the data collected are used to estimate models that, when applied to public data such as an economic census, estimate the FG for the study area (instead of estimating FG using only data collection, which requires larger samples). The net result of combining models and data is a dramatic reduction in the amount of data that needs to be collected.

The most striking feature of Table 3 is the huge difference between the per-capita FG for the large economies (i.e., United States, China, and EU-28) and the rest. The estimates show that per-capita FGs for the large economies are on average 3 times larger than those for Sweden (a high-income country with a vibrant export economy), and several times larger than those for the rest of the developing countries. This is a reflection of the size of the internal trade in these large regions, where large amounts of supplies are transported to other locations as inputs to subsequent stages of production processes. Another related factor is that the larger the geographic area under study, the larger the possibility of considering all the internal flows of cargo generated by the economy. For instance, the flows of coal and natural gas used to generate electricity end at power plants; from there, the electricity moves by power lines to rest of the country and metropolitan areas. As a result, freight surveys conducted in metropolitan areas typically do not include the transportation of the coal and gas used for electricity generation, while regional and national surveys do.

The results show that, generally speaking, the higher the income, the larger the total per-capita FG. As shown, the total per-capita FGs for the United States, EU-28, and Sweden are significantly larger than those for developing countries, which the exception is China. Again, this result confirms the interconnection between the economic activity and wealth, and the FG. A complementary perspective is provided by the per-capita FG for metropolitan areas, as they reveal the economic importance of their importance. As shown, large portions of the per-capita FG in metropolitan areas are associated with manufacturing, industrial, and construction activities.

The results for the various commodity types show that, despite the different scales and time periods, there is consistency among the estimates. In most cases, the per-capita FGs for the large economies are larger than those for the rest. Only in two cases, the per-capita FGs for metropolitan areas occupy one of the top two positions for a commodity group (i.e., base metal in Medellín and electronics in the tri-state area). In all other cases, the large economies occupy the top two positions. Reflecting the size of China’s manufacturing industry, this country has the highest per-capita FG in four out of five commodity groups (SCTGs 25-43), while the United States and EU capture the top positions in the others groups (SCTGs 01-24).

Among the developing countries studied, the per-capita FGs are in the same order of magnitude. However, and not surprisingly, the ones for Colombia—the most developed country in the group—are consistently higher than the ones for Bangladesh and the Dominican Republic. The results for the metropolitan areas are also consistent, notwithstanding the differences in levels of development and time.

Conclusion

The results presented in this paper provide a wide-ranging perspective on the demand for freight at different parts of the world, levels of geography, and time periods. Although hampered by the lack of publicly available data, differences in data collection methodologies, and unavoidable sampling and data errors, the results are remarkably consistent. Probably the most significant finding is related to the similarities between the per-capita FGs for geographic areas of similar size and income levels. As shown, most commodities exhibit rather similar values of per-capita FG. The cases where there are significant differences are typically the result of those commodities being major export products, which causes the per-capita FGs to be larger than usual.

The observation that per-capita FG generally increases with income has major implications, as it implies that, particularly in developing countries, economic improvements that lead to increasing income will produce large increases in the amount of freight produced and consumed and, subsequently, in the corresponding freight traffic. This, in turn, will aggravate congestion and environmental issues above and beyond what could be reasonably expected from the natural growth of population. Complicating matters even further, the surge of business-to-consumer transactions powered by e-commerce—accompanied by frequent deliveries of small shipments—is bound to increase congestion and emissions. There is a critical need to proactively find ways to ensure that freight activity can be conducted efficiently, but with minimal negative externalities.

Introduction

Road transportation is undoubtedly one of the most important modes in terms of the volume of passengers and freight moved all over the world, its contribution to GDP, and its impact on families' expenditure. It has also a key role in energy consumption, emissions, and contribution to climate change. Determining road cost functions is hence crucial for conducting a rational planning, and adopting policy measures aimed at improving the competitiveness of the economy and reaching a higher quality of life.

This paper begins with a brief explanation of the concept of cost and its different characteristics. Then, it makes a classification of road costs differentiating between infrastructure, vehicle operation, and personal costs. After that, it clarifies the difference between internal and external costs, and, on the basis of that difference, explains the concept of social costs. Subsequently, it describes the characteristics of the different road cost functions. This paper finishes with a definition of the concepts of economies of scale (EOSs) and scope applied to the road sector, and a description of the methods to calculate, allocate, and optimize the life-cycle cost of a road network.

The Concept of Cost

Costs are incurred when scarce resources are consumed, used, or worn. The loss or deterioration of these resources implies a reduction of utility for those who own them, and, as a consequence of that, for the society as a whole. Costs are sometimes valued using the concept of opportunity cost, which may be defined as the lost benefit of the next best activity forgone. In transportation economics, the value of travel time and reliability is often estimated on the basis of the opportunity cost ([Button and Verhoef, 1998](#)).

Fixed Versus Variable Costs

Costs can be split into fixed and variable ones. Fixed costs are those that do not depend on the output. Considering that the output of a road is the amount of vehicles that use it over its life cycle in vehicle kilometers (veh-km), and assuming that the capacity of the road is designed to provide a good level of service over its life cycle, the capital cost necessary to build the facility does not depend on the traffic volume so it may be considered a fixed cost.

Variable costs are those that depend on the output (veh-km). For instance, the wear of the pavement will depend on how many vehicles use the road, especially those with heavy axle weight. Similarly, fuel consumption and CO₂ emissions will be directly related to the amount of fuel fossil vehicles using the road. These items are classified as variable costs.

Short-Run Versus Long-Run Costs

The concept of fixed and variable costs depends on the time frame considered. The capital cost incurred is considered fixed in the short run, but not in the long run. To give an example, a highway originally built with two lanes per direction may provide a good quality of service for a period of time. However, let us say 10 years later, it may be necessary to add capacity by building an additional lane to guarantee a good traffic flow for another amount of years. Cost functions can be calculated for both the short and the long run. Long-run cost functions are usually calculated as the envelop of the short-run ones.

Infrastructure, Vehicle Operation, and Personal Costs

Getting into greater detail in the case of road costs, another distinction can be made among infrastructure, vehicle operation, and personal costs. Infrastructure costs refer to the costs necessary to keep the facilities available over the life cycle of the road. Vehicle operation costs refer to the cost directly incurred by the vehicles that use the infrastructure. Personal costs have to do with the loss of people utility associated to traveling.

Infrastructure Costs

Infrastructure costs can be divided into capital costs (usually known as CAPEX) and maintenance and operation costs (usually known as OPEX). Capital costs do not just refer to the mere construction of the facility, but also include other costs such as those related to the planning and design of the facility. These costs do not only comprise civil works, but also other auxiliary services such as intelligent transportation systems, etc. CAPEX are usually considered fixed in the short run, but they may experience changes in the long run. Capital costs are spent in a short period of time, but render service over a long period of time. This is the reason why, for accounting purposes, this cost is usually depreciated over the life span of the project.

The use of the road over the years along with weather conditions contributes to the wear and tear of the road assets. Maintenance costs intend to preserve the value of the assets over time to provide the right service to the users. They include both regular periodic maintenance and rehabilitation works. Periodic maintenance activities are those conducted on a regular basis such as, for instance, cleaning the ditches and drainages, painting signs, correcting minor deficiencies of the pavement, etc. Major rehabilitation works are conducted every several years, and they are aimed at preserving the patrimonial value of the assets ([Small et al., 1989](#)). Structural strengthening works to reinforce the pavement through additional asphalt layers and main works to repair bridges are considered major rehabilitation works.

Road operators incur other costs aimed to guarantee the availability of the infrastructure and its optimal functioning over time. These operation activities include snow removal, attention to incidents, withdrawal of objects in the road, signal management, etc.

Vehicle Operation Costs

Vehicle operation costs include the consumption of resources or damages to the environment and the society stemming from the use of the road by different types of vehicles. They comprise depreciation and financial cost of the vehicles, repairs, fuel and oil consumption, and tire wear. These costs depend not only on the characteristics of the vehicle, but also on the specific traffic flow conditions and the state of the road. For instance, fuel consumption per kilometer gets its optimal rate at a speed ranging from 40 to 90 km/h depending on the type of vehicle. Therefore, in congested roads, fuel consumption per kilometer gets higher. Similarly, deteriorated roads with high roughness levels bring about larger vehicle operation costs because of more frequent repairs, higher fuel consumption, and a more rapid depreciation of the vehicle. The HDM-IV model promoted by the World Bank provides relationships between the state of the road and the operation costs of the vehicles ([Paterson, 1987](#)).

Vehicle fleets of buses and trucks used by transport companies for business purposes also include the labor cost of drivers or other personnel necessary for carrying out their activities. These companies also incur indirect costs stemming from the managerial activities of the company. Indirect costs cannot be assigned to a specific output since they are common to all the activities of the firm.

Personal Costs

Personal costs comprise the individuals' opportunity cost of not being able to do something that has greater utility for them at that time. In the case of individual drivers or public transport passengers, this refers to the value of travel time and reliability ([De Palma et al., 2011](#)). The time spent within a vehicle cannot be used for other activities such as working, practicing sports, or going shopping. Again, the congestion of the road will imply trip delays that will directly impact the cost of time and reliability, thereby reducing users' utility.

Internal, External, and Social Costs

Internal Costs

Internal costs are defined as the costs directly borne by the users of the road—individual drivers, passengers, and transportation companies. They include most of vehicle operation costs such as fuel, vehicle depreciation, etc., and also personal costs such as travel time, reliability, etc. However, other costs, such as pollution, are not directly assumed by the users. If roads are not charged, infrastructure costs are external to the user as well. However, these costs may be internalized through pricing approaches aimed at making the users aware of them (Small, 1992).

Internal costs are also divided into costs that are perceived by the users and, as a consequence of that, influence users' decisions, and costs that, despite falling on the users, are not perceived by them. This might be for instance the case of the risk of having an accident. Even though users are aware of that risk, it is hard for them to perceive their ultimate consequences. The internal cost perceived by the users is also called the "generalized travel cost of transport," which is usually employed in transport modeling theory to explain users' behavior.

Cost borne by the users but not perceived by them usually lead to take wrong decisions. In the case a driver takes her car thinking that there is not congestion when actually there is a big bottleneck, she is taking a wrong decision not only for the society but also for herself. This is the reason why information is a key element to get to optimal solutions, notwithstanding the fact that people are not always rational. For instance, people do not necessarily use seat belts even though they know that it reduces the risk of getting hurt.

External Costs

External costs, or externalities, are those costs generated by the road system, both infrastructure and vehicles, but not borne by their ultimate producers, either users or companies. Those are for instance pollution, climate change, noise, and external damages of accidents. Externalities are recognized as a market failure that precludes optimal decisions without the right regulation. This is the reason why over the last few years, large efforts have been made to quantify these costs. In spite of all the effort conducted to that end, the values of different studies still diverge substantially (Link et al., 1999).

The cost of accidents includes material damages, administrative and medical costs, productivity losses, and the value of risk. Part of these costs is internalized through, for instance, insurance payments or damages anticipated by the users. However, a large proportion of accident costs is still considered external.

Most congestion costs are also external insofar as the damage produced by new vehicles entering a road stretch near to be congested is barely perceived by them. However, due to its specific characteristics, these costs will be described in greater detail later. Congestion costs as well as other externalities may be internalized in the short run through road pricing approaches.

Social Costs

Social costs are calculated by adding all the road costs borne by the members of the society: users, companies, government, and the rest of the population. The calculation of social costs should avoid double counting since some internal costs for a certain stakeholder may be benefits to other stakeholders. For instance, tolls are internal costs for road users, which actually influence their decisions, but, at the same time, produce revenues for the company or public authority that charges them. Similarly, taxes are not only costs for a company, but also revenues for the government.

Transferences, through prices taxes, etc., should therefore be excluded of the calculation of social costs. Determining the social cost function is of paramount importance to take right transport planning decisions by using for instance the cost-benefit analysis method.

Cost Functions

Production functions are simply equations for predicting the quantity of output as a function of all inputs' quantities such as fuel, employee hours, and vehicles. Cost functions are similar to production functions in that they predict the cost of production as a function of the output, and the prices of all inputs. A cost function represents the minimum expense necessary to produce a certain output (Jara-Díaz, 2007).

Total Cost

The total cost function shows the evolution of costs depending on a certain output. Considering that the output of a road is traffic, usually measured through veh-km, and assuming that all the vehicles that use the road have similar characteristics, the functional form of the total costs (TC) of a road in terms of traffic would resemble the shape displayed in Fig. 1.

As it was mentioned earlier, costs are different depending on the stakeholder that bears them. In the case of a road, it is crucial to focus on at least two types of costs: the social total cost (STC) painted as a continuous line in Fig. 1 and the users' total costs (UTC) painted as a broken line. The former intends to quantify the total costs borne by the whole society for a certain level of traffic, while

Figure 1 Total cost functions (social and users') for a road. *Source: Own elaboration of the author.*

the latter focuses just on the costs borne by road users. The first one is important for planning and project appraisal purposes. The second one is necessary to understand drivers' decisions since users decide on the basis of the costs borne and perceived by them.

The shape of the curves can be split into two different parts. From traffic zero to traffic t_A , traffic flow is fluid. As a consequence of that, total costs—both social and users'—grow linearly with traffic. The slope of the curve is steeper in the case of STC since externalities not borne by users—such as emissions, noise, and climate change—are included in this curve. The STC comprises also the fixed capital costs of building the infrastructure, which in the case of free roads are not paid by the final users. This explains the difference between STC and UTC when there is no traffic.

From t_A onwards, the road starts experiencing congestion since vehicles begin to disturb each other. According to traffic engineering principles, this effect produces a speed delay in the road, and henceforth greater travel time and a cost increase for the users and the whole society (Gómez-Ibañez et al., 1998). As long as the traffic volume goes up, the average speed in the road goes down. Therefore, the total cost curve gives up being linear to become concave. Again, the growth of the STC curve is more accelerated than the growth of the UTC curve. The reason that explains this phenomenon is that externalities are not borne by users.

Average Versus Marginal Cost and the Impact of Congestion

The total costs function provides a first understanding of the overall cost evolution in a certain road. However, for the purpose of planning, social evaluation and pricing a more detailed analysis through the calculation of the average and marginal cost curves are required.

The average costs curve is the result of dividing the total cost curve by output unit, usually defined in terms of traffic volume. The average cost can be calculated for either the social cost or the users' cost. The social average cost (SAC) shows the cost for all the society—externalities included—per traffic unit. The SAC encompasses all social costs including CAPEX and externalities produced. For low traffic levels this curve reaches very high values since the capital cost is split among few users. As Fig. 2 displays, the SAC gets lower as traffic increases till a certain traffic level t_0 where it reaches its minimum. From then on, the increasing costs due to congestion will offset the capital costs so the SAC curve will start growing. From the social point of view, the optimal traffic for the capacity of the road will be t_0 .

The average cost curve can be also calculated for the cost borne by the users (UAC). This curve is important since users take their decisions according to the average cost they bear as long as they perceive it. The UAC curve can be therefore considered the supply

Figure 2 Average and marginal cost functions (social and users') for a road. *Source: Own elaboration of the author.*

function for equilibrium in a road facility with no pricing implemented. This curve comprises only the costs actually borne and perceived by the users such as vehicle operation (depreciation, fuel, lubricants, tire wear, etc.) plus the disutility associated to travel time, reliability, and comfort. This curve can be calculated as the tangent of the angle that joins the coordinate axis with each one of the points of the UTC curve shown in Fig. 1. Before congestion, from traffic zero to t_A , the users' average cost will remain constant. However, once the capacity of the road starts getting constrained, average speeds will go down and travel times will become larger. This is the reason why from t_A onwards the UAC curve will start growing. This basically means that when users see how the speed of the road gets reduced, they experience greater disutility.

The marginal cost curve is also very important for transport economics. The economic theory states that if the supply curve coincides with the social marginal cost curve, the assignment of resources is optimal from the social point of view since the summation of consumer and producer surpluses is optimal. The marginal cost curve reflects the additional cost of producing an additional output unit. From the mathematical point of view, this curve is calculated as the derivative of the total cost function to traffic. The marginal cost curve has the property that it finds the average cost curve at its minimum. At the point where the traffic level reaches an optimal average cost, the marginal and the average cost curves meet each other.

Again, it is possible to calculate the marginal cost curve for both the social cost and the users' cost. The social marginal cost will be the derivative of the STC curve with respect to traffic. This curve is constant from traffic zero to traffic t_A since, if there is no congestion, the additional cost of a new vehicle will be the same as the average of the rest of the vehicles. The users' marginal cost is also constant from traffic zero to t_A . However, it will be located a little below the SMC curve since it does not include the marginal cost of externalities. From t_A onwards, the marginal cost will start increasing in a rapid way. Again, the growth of the SMC is more accentuated than that of the social marginal cost.

It is worth to note that from t_A onwards the UMC curve grows more rapidly than the UAC curve. This means that, when congestion problems appear, each user perceives a cost that is lower than the marginal cost inflicted to the rests of the users of the road (Small, 1992). This is the reason why congestion is usually considered an externality, which could be internalized through road pricing strategies.

Supply Versus Demand Equilibrium

The cost curves are also crucial to understand the equilibrium between supply and demand in a certain road. Fig. 3 shows the behavior of three demand levels for the same infrastructure: low demand (D_L), medium demand (D_M), and high demand (D_H). If no price is set, the natural equilibrium will happen when the demand curve and the UAC curve meet since this curve reflects the cost actually borne by the users.

Fig. 3 shows that the traffic flows of equilibrium for the three demand levels are not optimal according to welfare maximization criteria. The optimal welfare that optimizes the summation of consumer and producer surpluses would happen when users actually perceive the social marginal cost they produce. To reach a first best optimal outcome is necessary to introduce different prices depending on the level of demand (p_L , p_M , and p_H). Those prices will imply reducing the natural traffic flows of equilibrium t_L^n , t_M^n , and t_H^n to the optimal flows of equilibrium t_L^o , t_M^o , and t_H^o . It is noticeable that, once the road begins to get congested, optimal prices get higher so optimal traffic flows diverge to a greater extent of the natural ones. This happens because, once the capacity of the road starts getting constrained, the additional cost produced to all the users by a new vehicle entering the road is higher than the average cost perceived by that driver.

Another interesting aspect is to determine to what extent optimal prices are able to cover the average costs produced which are not internalized by the users. These costs mostly include infrastructure costs (construction, maintenance, etc.) and externalities. For each traffic level, these costs are the difference between the SAC and the UAC curves.

Fig. 3 shows how, for low demand levels, the price p_L is not able to cover the costs not internalized by the users (SAC-UAC). As a consequence of that, this price will not be able to finance the infrastructure costs. The medium demand level, which for the case of

Figure 3 First best optimal prices for different demand levels. Source: Own elaboration of the author.

Fig. 3 is depicted on purpose coinciding with the minimum of the SAC curve, shows that the optimal price p_M fully covers the cost not internalized by the users. In this case, the price will be able to fully finance the infrastructure costs. It is worth to mention that this production level also coincides with the minimum average cost. Demand level D_M is therefore the optimal one for the physical characteristics of the road. At this point it is appropriate to mention that the optimal level from the economic point of view still requires a certain degree of congestion and externalities. Finally, for the high demand level D_H , the optimal price p_H exceeds the costs not borne by the users. This fact proves that, for such a demand level, the infrastructure gets small so, even though in the short term setting a price p_H to the users is a good solution, in the medium term an expansion of the capacity of the road will likely be the best solution. This is a simple explanation of what is called the “self-financing theorem” (Mohring and Harwitz, 1962).

Economies of Scale and Scope

EOS indicates what happens to average costs when scaling up production. A road can experience either (rising) EOSs, constant EOSs, or diseconomies of scale depending on how average costs change as output, such as vehicle miles traveled, increases. EOSs indicate average cost savings per unit as output goes up. According to Fig. 2, the production of the road has rising EOSs from traffic 0 to traffic t_0 . This means that traffic increases in that range will always imply lower SACs. However, from t_0 onwards, because of congestion, the road will have diseconomies of scale.

Economies of scope or cost complementarities are economic factors that make the simultaneous manufacturing of different products more cost-effective than manufacturing them on their own (Jara-Diaz, 2007). In the cost functions described earlier, a single traffic vehicle is considered. However, a road is usually utilized by different types of vehicles, such as cars, buses, and trucks, that produce a different cost per output. In most cases, the average cost of a single road that is used by both cars and trucks simultaneously, especially if there is no congestion, is lower than having two parallel roads, one for cars and one for trucks. This is a clear example of the application of the concept of economies of scope to the road sector.

Cost Calculation, Allocation, and Optimization

Cost Calculation

There are usually three methods for estimating cost functions: accounting, engineering, and econometric. The accounting method is based on taking advantage of the accounting procedures used by organizations to keep track of expenses according to detail categories. The engineering one is based on taking advantage of the knowledge of technology, operations, prices, and quantities of inputs. Engineering models can reach a high level of detail so they can be used to examine the performance of complex systems. The econometric approach is based on calibrating a model on the basis of the information available aimed at determining the impact of certain variables in cost production functions. The functional form usually implemented to calibrate these models is the translog function. This functional form provides a second-order numerical approximation to almost any underlying cost function at a given point.

Cost Allocation

As it was previously mentioned, a road network has cost complementarities for different types of vehicles such as cars and trucks. For some reasons, such as setting a fair price to each vehicle category, it is necessary to allocate road costs to different types of vehicles. This may be easy for costs that are directly attributable to the vehicle such as the wear and tear of the pavement, fuel consumption, of pollution. However, cost allocation may be more complicated for fixed costs such as CAPEX, or accidents where both a car and a truck are involved.

There are two types of allocation procedures for breaking down global costs to vehicle types: deterministic and probabilistic. The deterministic method consists of assigning costs according to certain characteristics of the vehicles on the basis of engineering criteria. For instance, pavement wear and tear costs are usually associated to the axle laden weight of the vehicle. The probabilistic or statistical method, which is usually combined with deterministic methods, is based on setting up functional equations estimated by econometric approaches.

Life-Cycle Cost

The planning process for road investment is aimed at optimizing costs and benefits over the life cycle of a certain asset. The cost component of the road is of paramount importance for the optimization process. Life-cycle cost analysis enables to determine the most cost-effective option among certain alternatives including design, construction, financing, maintenance, operation, and, if necessary, demolition of the work. All the costs are usually discounted to a present-day value.

Life-cycle cost analysis is founded on the fact that different types of cost are not independent from each other. For instance, the capital cost of the infrastructure will influence the maintenance cost. Similarly, the maintenance cost will have an impact on the operation costs of the vehicles. The goal of the life-cycle cost analysis is to find out the optimal combination of costs for the society over the life of the project.

Introduction

Cities and urban areas have historically been places of trade and commerce that generate a significant amount of freight. In addition to growing levels of manufacturing in urban areas, rapid urbanization in the future will create increased demand for freight relating to the distribution of food and consumer goods as well as transport of construction materials for new residences and infrastructure.

This article discusses current and future challenges confronting urban freight systems and useful approaches for addressing them such as City Logistics and the Physical Internet. Suggestions for how emerging technologies could be implemented in the future to improve the efficiency and sustainability of urban freight systems are also presented.

Challenges

Since goods are generally stored, processed, and consumed at different locations in urban areas, there is a need for goods to move to increase their monetized value for producers, manufacturers, and consumers. Consequently, freight is a derived demand, that is, it does not exist for its own sake, the primary demand is for the production, manufacturing, and consumption of goods. Freight therefore, can be considered as the economy in motion.

Population Growth

Urbanization is a global trend that is predicted to continue for some time. Over half of the world's population currently lives in cities and the urban population of the world is expected to increase by more than two-thirds by 2050 (UN, 2018). Population growth in urban areas will present substantial challenges as future urban freight systems will have to address rising levels of road congestion, that is, threatening efficiency, reliability, and sustainability.

Many cities are currently experiencing pressure on existing infrastructure. Urban freight systems will have to adapt to the limited capacity of future road and rail networks that will be similar to current levels. Associated with population growth in urban areas will be the increase in the size of metropolitan regions. As cities grow spatially, addition distances are required for transporting goods.

Logistics sprawl, the phenomena where logistics facilities, such as warehouses and distribution centers in inner or central areas of cities are relocated to the fringe of urban areas, can create increased transport when ports and high proportion of the population are

located in central areas (Aljohani and Thompson, 2016). In the future, land-use planning will need to address this by protecting and preserving logistics facilities in inner urban areas to reduce the amount of intra urban freight transport.

eCommerce

Increased level of service expectations due to eCommerce (especially B2C), just-in-time manufacturing and rapid response retail logistics is increasing the number of freight movements using vans and small trucks. There is a growing trend for receivers to be able to nominate narrow time windows that makes efficient distribution routes difficult.

Lower levels utilization levels of the load capacity of vehicles (both weight and volume) is a common trend due to higher levels of service demanded by shippers and receivers. More frequent, smaller consignments are leading to an increased number of freight vehicles on urban roads adding to emissions and congestion. Creating more resilient transport networks that can improve reliability from disruption due to incidents, extreme weather, and construction projects will be necessary in the future.

To improve urban freight systems in the future, initiatives will need to increase productivity levels and efficiency for carriers as well as provide higher levels of safety and enhance amenity for residents.

Safety

Reducing road trauma from truck-related crashes is a major challenge. In many cities, there is a recent trend toward more cycling and walking, especially in central city areas. This increases conflicts between vulnerable road users and freight vehicles.

Health and Well Being

Truck emissions are a substantial contributor to air pollution in urban areas. A major challenge is how to decarbonize urban freight to reduce emissions and improve health for residents (ITF, 2018). Although urban areas can provide high levels of liveability, many residents can be exposed to high levels of emissions and noise from freight vehicles that can be detrimental to health (WHO, 2016). Urbanization is increasing the exposure to noise and air pollution.

Traffic noise can elevate cardiovascular disease, cognitive impairment in children, sleep disturbance, tinnitus, and annoyance. Environmental noise from road traffic has been shown to increase stress levels, heart rate, blood pressure and ischaemic heart disease. In addition, high residential traffic exposure as well as road traffic noise has been associated with hypertension. Noise that disrupts sleep has been recognized as having a major health impact.

Diesel engines produce four main pollutants, carbon monoxide-CO, hydrocarbons-HC, particulate matter-PM and nitrogen oxides-NO_x. Ambient air pollution is a major factor in stroke, ischaemic heart disease, lung cancer chronic obstructive pulmonary disease and acute respiratory infection. Diesel emissions from trucks have been found to be a major contributor in urban areas.

Current methods often measure the effects of air pollution in terms of particulate matter (PM), and increases in both mortality and morbidity have been detected at existing ambient PM concentrations. Significant health impact of pollution can therefore be expected in urban centers throughout the world, as exposure to PM is ubiquitous.

PM is emitted from diesel engines. PM_{2.5} (particulate matter less than 10 µm) is believed to be a greater health threat than PM₁₀ (particulate matter less than 10 µm) as the smaller particles are more likely to be deposited deep into the lung. Eliminating diesel and adopting electric vehicles is a trend that is promising but due to the higher financial costs the uptake is slow in many cities.

Consolidation

Achieving high levels of consolidation is a growing challenge in urban freight. Just-in-time manufacturing, rapid replenishment retailing, and eCommerce driven by omni-channel logistics are all contributing to small loads being transported by trucks and vans in urban areas. Currently most freight trips only carrying a small percentage of their carrying capacity. There is also a large proportion of unladen trips traveling back to or from depots without any load. Repositioning of empty shipping containers can also account for a substantial amount of truck traffic in some cities.

Adapting to the Digital Economy

The fourth industry revolution that involves transitioning to a digital society will require a multi-disciplinary approach that will bring together a range of disciplines including engineering, computer science, and business. How supply chains and logistics adapt to the digital economy will have a profound influence on urban freight systems. A key issue for urban freight systems will be how information-based technologies can be designed and implemented to improve efficiency, productivity, and sustainability while not threatening values, such as security, privacy, and safety.

Achieving the Sustainable Development Goals

The United Nations Sustainable Development Goals (SDGs) provide useful directions relating to how urban freight systems can support more sustainable cities as well encouraging more responsible consumption and production.

City Logistics

To address the growth in negative impacts of freight in urban areas the field of City Logistics was developed in the late 1990s. City Logistics provides a framework for developing and implementing initiatives aimed at reducing the total costs associated with freight in urban areas, including externalities, such as emissions, crashes, congestion, and noise (Taniguchi et al., 2001).

City Logistics considers urban freight as a complex system. It is important to consider that the primary purpose of an urban freight system relates to its role in providing a service for the economy. The urban freight system allows access to markets for exchanging goods. Thus, the primary objective of urban freight systems is to maximize efficiency (benefits relative to costs). However, City Logistics considers the social and environmental as well as the economic costs of urban freight.

City Logistics is based on the systems approach, where problems are identified and new solutions or schemes are designed, evaluated, and implemented. Involvement by key stakeholders: shippers, carriers, receivers, administrators, and residents are central in City Logistics. The roles and objectives of all stakeholders are considered. Partnerships between stakeholders are encouraged. The Freight Quality Partnership (FQP) program developed in the United Kingdom provides a useful structure for developing effective partnerships for solving urban freight problems (Browne et al., 2004). Such programs allow administrators and private industry to interact and work together to solve complex problems. This involves sharing information, exchanging perspectives, and developing trust between stakeholders.

City Logistics aims to strengthen the goals of cities relating to liveability, mobility, and sustainability particularly when these goals are threatened by freight. City Logistics embraces the free-market economy. Competition is considered crucial for encouraging innovation and improving efficiency. Voluntary participation in initiatives is promoted in contrast to regulation. Advances in information systems are promoted. Traffic management systems aimed at improving the network efficiency and productivity of freight vehicles, are an example of this.

A broad evaluation of a wide range of impacts for all key stakeholders is considered in City Logistics. This considers multiple criteria, encapsulating the different goals and objectives of stakeholders. Recent advances in multi-criteria evaluation methods and Multi Actor Multi Criteria Analysis (MAMCA) allow investigation of the trade-offs between stakeholders to be considered (Macharis et al., 2012).

During the last 2 decades, a number of City Logistics Solutions (CLS) have been developed and implemented in many cities throughout the world. Common solutions include, Urban Consolidation Centers, Joint Distribution Systems or Cooperative Freight Systems, and Off-Hour Deliveries. CLS provide useful initiatives for addressing future urban freight issues. It is important that City Logistics principles be adapted to solve local problems. CLS need be designed and implemented to suite local conditions, given the diverse range of social, political and technological systems that exist between cities.

Urban Consolidation Centers (UCCs) are logistics facilities that are situated in close proximity to a city center, a town or a specific site such as a shopping center. Instead of carriers delivering directly to receivers, goods are dropped off at the UCC, where the goods dropped off by carriers are sorted and consolidated to make deliveries to the final destinations, often using environmentally friendly vehicles.

UCCs address how to increase consolidation levels in freight vehicles that is a key to achieving sustainable urban goods transport. Increasing consolidation for last kilometer reduces unnecessary vehicle movements, and thus congestion and pollution. UCCs have a number of advantages including environmental and social benefits.

Future UCCs will need to be compatible with wider public policy and regulatory initiatives such as access restrictions and loading bay restrictions. For UCCs to be successful they will need to be developed with more orientation toward receiver requirements. Potential for better inventory control, product availability and customer service, and better use of resources at delivery locations as well as opportunity for carrying out value-added activities will drive their adoption.

Due to the high set up and operating costs, the public sector will need to support such initiatives by providing space and enforcing regulations for vehicles not included in consolidation schemes. Open facilities that encourage an exchange of goods between multiple carriers and different modes will be required.

A courier hub has been established in Sydney that provides cages and lockers to exchange goods and parcels for collection and distribution in the central business district. The State government provides free access to this facility for carriers. The courier hub promotes the transfer of goods between vans, bikes, and trolleys.

The Binnestadservice (inner city service) is a scheme that is growing in the Netherlands and other European countries that combines UCCs with a joint delivery service (Quak et al., 2018). When small retailers join, their suppliers are sent the UCC address for carriers to deliver goods to. This scheme deliberately focuses on small and independent retailers with goods delivered when the retailer wishes. Additional services include storage, home deliveries and reverse logistics (waste). A variety of clean vehicles, including electronic bicycles, natural gas trucks, and electric vehicles are utilized.

Off-Hour Deliveries

In future, there will be a need for road infrastructure capacity be used more imaginatively on a 24-hour basis. Recently, a number of major cities (e.g., New York City, London, and San Paulo) have promoted deliveries made during the off-hours (7:00 p.m. to 6:00 a.m.). Off-hour deliveries (OHDs) can either be staff assisted where receivers are present at the time of delivery or unassisted where unsupervised access to the establishment is provided. OHDs aim to reduce congestion and pollution during daytime hours. They have been shown to reduce congestion on main roads and provide substantial travel time savings for carriers. Although there are

potential noise problems for residents from trucks at night, these can be generally overcome by using quieter vehicle technologies as well as improved driver training.

City administrators can encourage more efficient city logistics by providing incentives for vehicles with high load factors, for example, preferential access to loading zones or reservation systems at loading docks as well as providing facilities that create opportunities for transferring goods between modes, such as trucks, vans, and bikes as well as short-term storage.

Physical Internet

The Physical Internet (PI) is an emerging paradigm for planning and managing freight and logistics networks (Montreuil, 2010). It aims to transform the way physical objects are moved, stored, realized, supplied, and used in the pursuit of global logistics efficiency and sustainability. Key elements of the PI are, open and shared networks, standardized and modular load carriers, track and trace protocols, and certificates. The PI requires new business models for sharing assets. Supply network coordination, synchromodality, and information technology are employed for improving the safety and sustainability of supply chains.

PI aims to achieve the right modes and load factors for the right loads that requires compatible load units and coordinated transfers between modes. This involves integrating vehicles, loads and transshipment facilities.

Hyperconnected City Logistics (HCL) combines concepts of the Physical Internet and City Logistics. Within cities, terminals are required for transferring loads between vehicles as well as temporary storage allow consolidated loads on vehicles. To achieve high levels of service, efficiency and productivity, a range of vehicles are used to transport goods between terminals as well as servicing local areas. Bikes, trolleys, and vans can be utilized to collect and distribute goods in areas near terminals, while rail and larger trucks can be used to transfer goods between terminals.

Parcel Lockers

Parcel lockers provide cheap, flexible, and convenient facilities for exchanging small goods as well as reducing the economic and environmental costs associated with eCommerce. Parcel lockers are likely to become more popular in the future, since they have much lower rates of delivery failure for Business-to-Consumer (B2C) and allow consolidated deliveries to locker banks for carriers as well as having lower costs of distribution for carriers in metropolitan areas. Open systems that allow multiple carriers to access locker banks will become more prevalent as they will further reduce costs for carriers.

Shared parcel lockers will also provide an opportunity for more efficient and sustainable Business-to-Business (B2B) courier deliveries in high-density areas such as Central Business Districts (CBDs). Various modes (including walking and bikes) can be integrated to reduce the financial and environmental costs of delivering and collecting parcels. Parcel lockers provide an opportunity to transfer goods between modes as well as carriers. Trucks and vans can be used to carry parcels to locker banks and these can then be picked up by couriers for delivery to the final customers within a precinct or area of the CBD. Walking and cycling will become more popular in central city areas as they are often more productive in performing the last kilometer of deliveries.

Reservation Systems

Loading dock booking or reservation systems will become more common for managing loading docks at activity hubs, such as shopping centers and residential towers. Digital and telecommunication technologies can be used to exchange information between stakeholders including shippers, carriers, receivers, facility managers, and road managers. With booking systems, supply chain communities become more visible and less time is spent manually coordinating deliveries.

Developments in the Internet of Things (IoT) can facilitate access control to dock areas and spaces, thus improving security. Booking systems save delivery firms and their customers' time and money as queuing times can be eliminated. Dramatic reductions in truck idle time at the street level can be achieved.

Booking systems lead to more efficient operation of loading docks and avoid congestion in city streets. Receiving operations for all shipments to and from a distribution location can be optimized by taking into account the type of vehicle, type and quantity of load, individual dock availability, and site operations policy.

On-Line Auctions

On-line auctions provide a means of matching supply and demand in a dynamic way to increase the utilization of vehicles and operating costs. Such systems also allow shippers to outsource to have their transport and avoid having to have their own fleets.

Shared Freight Systems

Freight systems in many metropolitan areas are typically characterized by suppliers operating their own vehicle fleets, distributing only their goods to their customers. There is an opportunity to combine freight networks to reduce the number of vehicles required as well as the distance traveled by freight vehicles. This can result in substantial savings in operating costs for carriers as well as reduced emissions and noise from freight vehicles.

There is a considerable degree of inefficiency relating to the transport of general freight within large metropolitan areas. It is common for not-for-hire and reward carriers to transport small and moderate loads across urban areas often in small vans and medium-sized trucks, with the vehicles generally not carrying freight on the return trip.

In future, high-capacity freight vehicles frequently operating between freight intensive or industrial areas with hubs created to transfer and tranship loads between vehicles to transport goods from shippers to receivers could be implemented.

A substantial amount of general freight transport occurs within metropolitan areas for production, processing, wholesaling, and retailing. General freight is typically stored in boxes and stacked on pallets when being transported. In the future, general freight from a number of shippers could be combined in large freight vehicles to increase vehicle utilization.

Shared freight networks have the potential to reduce the amount of freight vehicles traveling in metropolitan areas. Consolidated loads can often be delivered by fewer vehicles with reduced distances traveled. This can help counter the additional transshipment costs. Voluntary co-operation within specific sectors of the private sector seems to offer good potential for being a successful City Logistics scheme.

The shared urban freight systems of the future will need to be designed considering the network effect that relates to the increased benefits that are created when more users utilize a service. This has been successfully applied to urban public transport systems where hubs are used to transfer passengers between feeder services with high capacity and high frequency services. The same concept can be adapted to the movement of urban freight. The network effect is realized when more shippers and carriers utilize the shared system creating substantial operating cost savings due to the high degree of consolidated loads in vehicles transferring goods between hubs.

A higher degree of coordination between modes will be possible in the future when information can be shared easier. Synchromodality involves a flexible and sustainable allocation of cargo to various modes and routes in a network so that the shipper or forwarder is offered a real-time integrated transport solution (Tavasszy et al., 2017). This involves systemic thinking, focusing on available capacity (regardless of mode of transport). Blockchain related technologies will facilitate shared and more coordinated systems in the future.

Technology Opportunities

The digital economy will be largely influenced by advances in data, networks, and automation (DNA). Big data can be captured from the proliferation of low cost and connected sensors. Track and trace systems will allow unprecedented transparency and monitoring of freight. Developments in deep learning and cognitive computing will allow a richer understanding of demand patterns, levels of service, and impacts to be achieved.

The proliferation of sensors will create many opportunities for improved forecasting and automated systems. Artificial Intelligence (AI) based methods including machine learning will allow urban freight systems to be more efficient by anticipating demand and managing capacity in real time.

Developments in automation will allow more intelligent and autonomous systems to be developed. This will lead to lower freight and logistics costs since labor rates are high in many urban areas. Tasks such as sorting, packing, and even driving will be automated. This will lead to improvements in safety and reliability.

Although robots and drones offer many benefits for urban freight systems, their successful implementation will depend on how issues associated with security, privacy, and safety can be overcome to gain community acceptance.

Freight vehicles operating in urban areas will become more automated, connected, electric, and shared (ACES) in the future. Cleaner, low noise and more energy-efficient vehicles will improve sustainability and liveability.

The rollout of integrated information technologies will provide many opportunities for enhancing the performance of urban freight systems. Next generation traffic management systems will allow many freight-oriented services to be developed.

Advanced sensing and communication technologies such as Dedicated Short Range Communication (DSRC) allow freight vehicles to communicate with other vehicles as well as infrastructure. The ability of freight vehicles to be incorporated in future traffic management systems will enhance sustainability. Connectivity between trucks and signal systems will lead to significant improvements in efficiency, as most delays for trucks in cities occur at signalized intersections.

It is common for trucks to be delayed due to slow acceleration from stops. Signal systems currently are unable to be responsive to freight vehicles and their loads in real time since they do not communicate or respond to individual freight vehicles, leading to frequent braking, acceleration, and stopping. Future traffic signal systems will be able to adjust offsets, extend green times, and/or provide advisory speeds for drivers to ensure that stopping is minimized. Significant reductions in travel times of trucks along a corridor will be able to be realized. Savings in fuel consumption and vehicle wear and tear for carriers will be able to be achieved. Residents will also be exposed to lower noise and emission levels. Detection of trucks and vans as well as their loads could also allow priority for freight vehicles based on their utilization.

Advanced traffic management systems will be able to provide information regarding road closures and network disruptions from roadworks, signal faults, and construction zones. There will also be opportunities for improving safety of pedestrians and cyclists around trucks. It will be possible for alerts to be issued to drivers concerning vulnerable road users in vicinity of trucks.

Traffic sensor networks will permit more accurate short-term predictions of travel times between origins and destinations on urban traffic networks to be produced. Thus, predicted arrival times will be more accurate by being updated to reflect actual and predicted traffic network conditions. Updated predictions of the expected time of arrival (ETA) be available during the trip based on the estimated demand on the traffic network.

Loading Bay Management Systems

A substantial amount of time for couriers in central city areas involves conducting walking routes between vans and receivers. Future systems will be optimizing courier routes and be able to reserve loading bays to ensure that traffic congestion and delays are minimized.

3D Printing

3D printing allows specialized components and products to be made on-site and on-demand. This largely eliminates distribution and storage of goods and minimizes packaging.

Conclusions

Rapid urbanization is creating many challenges for improving the efficiency and sustainability of urban freight systems. Approaches such as City Logistics and the Physical Internet provide frameworks for ensuring that future solutions will be more integrated and address social and environmental issues. Emerging technologies have the potential to improve the performance of urban freight systems but to gain acceptance by communities they will need to ensure that values such as privacy, security, and safety are not compromised.

Introduction

The operation cost corresponds to the production cost of transportation. In the specific case of public transportation, the operation cost is the cost incurred by the firm or public agency that provides the service and manages a fleet of either buses, trains, or a mix of both. Like any economic cost, in its definition is implicit the idea of minimization of the expenditures needed to produce a given level of transport output and input prices. This minimization of expenditures implies an optimal allocation of all the input factors used for transport production.

The economic analysis of operation costs is relevant for policy design and procurement of public transport services by governments. Usually, the design of regulatory policies needs to know the industrial structure of the public transport industry. For that purpose, the studies are led by economic theory and conducted by using statistical data and econometric methods. The usual approach is the estimation of a cost function. In this case, the objective is to identify critical parameters describing the industrial structure such as degree of scale economies, density economies or size economies, average and marginal cost, and marginal rates of substitution of inputs. This information can be used to define the type of regulation, the fare level, or the need and level of subsidies, for example.

Practitioners, however, use accounting cost studies to deal with the procurement of public transport service and contract design. These studies are not based on the economic theory and use the account cost of the firms or public agencies to establish a relationship between cost and some measures of supply-oriented output (see discussion on types of outputs next). For instance, the regulator can assume that the total cost is a linear combination of vehicle-kilometers, vehicle-hours, peak vehicles in services, and route lengths. The coefficients of this linear model are used to set the payment to the firm (or transfer to the public agency) for the provision of the service in a contract.

The formal economic analysis of the operation cost of public transport addresses three main issues (Gagnepain et al., 2011). The first issue is a description of the technology behind the industry in economic terms by measuring economies of scale, density, and scope. The second issue is a definition for the output, either supply indicators (e.g., vehicle-kilometers or seat-kilometers), demand related output measures (e.g., passenger-kilometers or the number of passengers) or multidimensional output. Finally, the third issue is the evaluation of firms' performance through a measure of the technical efficiency level.

Inputs for Public Transport Provision

The main input factors used to produce public transport are capital, labor, and energy. The capital consists of buses, trains, and bus garages. The infrastructure needed for trains is not part of the capital as it is shared with other services, like freight transport, similar to the streets for the buses. However, some authors consider the network as an input for transport production as the output depends on its structure.

The labor comprises of the human resources needed for the operation and maintenance of vehicles, stations, and depots, and the management of the firm or public agency in charge of the public transport provision. The energy consists of combustible or electricity needed for the operation of the vehicles. The importance of input factors in the total cost depends on the type of public transport and the location of the network it operates. In the case of buses, labor share is between 20% and 60%, depending on the country (White, 2018). For instance, the share of labor can reach 60% in London, around 40% in Santiago, and around 20% in India. Several factors determine the level of labor cost. For instance, the average income per capita in the network location determines the level of wage. The number of persons and the level of qualification required by the staff (especially drivers) depend on the type of vehicle (buses, trams, or trains) because the person's skills are different. The level of regulation of the industry also affects the labor cost because the unregulated networks tend to operate informally (for instance, in developing countries) with low administrative staff and unqualified drivers, and regulate networks tend to operate under strong labor rules and unions (e.g., Europe).

Capital cost comprises of vehicles and infrastructure. In the case of vehicles, the cost varies widely because the network can be operated with very different types. For instance, small, low-technology buses imply low capital cost, but high-technology trains imply high costs. Also, the technology and vehicle determine the capital cost related to infrastructure as depots and garages. The capital cost also depends on the interest rates for financing the investment, which in turn depends on the level of risk. For instance, in

developing countries with unregulated transit systems, the operating firms are small companies composed of many owners of one or two buses organized into unions. These firms get high-interest rates because of the low bargaining power and the high risk due to intense competition and weak regulatory institutions. In regulated transit systems, usually, there are one or few operating firms, which access to the low-interest rates because of the government gives subsidies or guarantees the debt. The capital cost also depends on the country's capacity to produce the vehicles and the competitiveness of the vehicle industry. This competitiveness is particularly relevant for the trains because a few countries are manufacturing it.

The cost of energy is usually related to the prices of electricity and diesel. The price of both inputs depends on the country where the public transport service operates. Some factors affecting these prices are the fuel tax policy, the level of domestic oil extraction, and the sources of electricity generation (e.g., coal, natural gas, hydroelectric, nuclear).

The operation cost also depends on the network structure (Jara-Diaz, 2007). One obvious way that the network affects the operation cost is its composition in terms of the type of vehicle and technology: buses, trains, or tramways, for instance. Another less obvious way is the network's topological structure. This structure depends on the connections of the lines of either bus, tramway, or train (subway or light rail). For instance, a bus network has a structure of direct lines if the bus routes connect most of the origins and destinations without transfers. This type of network is common in cities with deregulated public transport, where many firms deliver services independently. In turn, a network has a feeder-trunk structure if there exist several high-capacity services, such as subway or BRT, which operate in main roads and connect zones with lower demand (or lower residential density) by buses or other low-capacity vehicles. This structure is typical in cities with one or a few bus companies, where there exists an integrated fare with a unified payment system like electronic cards.

If the operating firm keeps the network structure fixed when optimize its operation allocating inputs for a given level of output, we need to recognize that the operation cost is conditional on this network structure. However, if the firm chooses the input allocation and the network structure, the cost is the global operation cost and is less or equal to the conditional operation cost.

Another essential factor for producing transport is the users' time. Indeed, the participation of users is necessary to produce final transport output, such as trips. The inclusion of users' time as input is relevant for public transport policy design. In this case, the (benevolent) transport planner takes into account the monetary cost of public transport provision and the users' cost (time). Several authors have shown that the inclusion of users' time as input led to substantial economies of density in public transport provision (Mohring, 1972) and, thus, marginal cost pricing will require subsidies. Besides, if the motivation is the study of the industrial structure to design regulatory policies, the users' time is less relevant in the operation costs as the focus is on the firms' behavior. They do not take into account users' time directly when making decisions on the operation, pricing, or merger, but through the demand, if it is elastic to either waiting, accessing or in-vehicle time.

The Output of Public Transportation

The formal economic analysis of transportation costs must consider multiproduct firms. This feature implies the output is a flow vector, with components identified by origin, destination, period, and commodity type (Jara-Diaz, 1982; Winston, 1985). Such an output disaggregation is infeasible for public transport because the number of origin-destination pairs is too large. For instance, if a bus service passes through ten different zones in a city, the vector of output should have 45 components, if there are three periods: morning peak, off-peak, and afternoon peak, the output vector should be of 135 components. Each component is the number of carried passengers from an origin to a destination. Then, the study of the operation cost needs information on the demand for every component. Moreover, the cost in one origin-destination pair depends on the output in other pairs. The complexity implied by the disaggregate output leads to study operation costs using aggregate measures of output such as total passenger, total driven kilometers, passenger-kilometer, seat-kilometer, or vehicle-kilometer.

Among the aggregate measures of output, we can distinguish two types: supply-oriented output, and demand-oriented output. The supply-oriented outputs are those measures related to the transport capacity delivered by the operators without involving the number of carried passengers. For instance, the seat-kilometers supplied in a month by a subway company, or the bus-kilometers supplied by a bus line. Other standard measures of supply-oriented output are total driven kilometers, total seats, seat-hours, vehicle-hours, and peak vehicles in service.

These output measures are also called intermediate output because to produce the final output, which is carrying passengers, it is necessary to provide seats, driven kilometers, and vehicles.

The demand-oriented output is a measure of the final output, which means the measure involves the carried passengers in some way. Standard measures of demand-oriented output are total passenger and passenger-kilometers. In regulated networks, some times, the operator's farebox revenue is a measure of the output because this information is available from the periodic reports required by regulators (for instance, Gagnepain and Ivaldi, 2002). When the information of carried passengers is not always available or is not reliable, the analysis of operation cost uses supply-oriented output or indirect measures of passenger demand. For instance, Batarce (2016) uses a transit network assignment model to compute the demand for every bus service and estimate the marginal cost in Santiago's bus transit system.

However, the aggregate measures of output are not enough to describe unambiguously the operation costs, which depend on several variables other than output and inputs. Some of these variables are related to the operation itself and some others related to exogenous conditions. For instance, among the first group of variables, the bus frequency or the headway determine the fleet and the labor (bus drivers), which may be different for the same aggregate output level. The bus capacity is another variable in the first group

that determines the operation cost. An exogenous variable is the distribution of the demand on the service route. If the demand concentrates on a few route segments, the required capacity to meet the demand is higher than the required capacity for a uniformly distributed demand. The demand concentration, in turn, depends on the population density in the city. Another exogenous variable is the distribution of the demand along the day and the concentration on the peak hours. Also, the congestion on peak hours affects the bus operation costs as the lower commercial speed, the larger the necessary fleet to fulfill the frequency and provide the capacity to meet the demand.

In consequence, operation cost estimation with aggregate output measures could result in biased estimates. To overcome this problem, [Spady and Friedlaender \(1978\)](#) proposed a hedonic output approach that defines the output as a function of a vector of aggregates. Components of this vector measure different characteristics and technological factors of output. For instance, some output characteristics that may be included in the hedonic function specification are the number of stops on the route, average passenger load, average trip length, and route length. Similarly, a way to deal with disaggregate output is allowing the cost function to depend on few aggregate measures of output and some descriptors of the operating environment (e.g., route length) (see [Basso et al., 2011](#)).

Economies of Scale, Density, and Scope

As mentioned, the analysis of firms' technology in economic terms is a relevant issue when studying the operation costs of public transportation. This technology is mainly characterized by the degree of economies of scale, scope, and density.

To understand what economies of scale and scope are, consider a vector of disaggregate output from a public transport firm $y = (y_1, \dots, y_n)$. In general, the output vector components are different products. The public transport firm's output vector is composed of passenger flows between different origin-destination pairs served. For instance, if the firm operates a bus line that serves five zones in a city in a one-way cyclic circuit, the vector would have $n = 20$ components because every zone connects all other zones. The output vector might also be composed of passenger flows in different periods or another disaggregation relevant to the firm's cost structure.

The standard definition of increasing returns to scale is that if inputs are all increased by the small factor $\lambda > 1$, then output increases by a factor larger than λ ([Panzar and Willig \(1977\)](#) show that the degree of economies of scale in multi-output production is $A = C(y) / \sum_{i=1}^n y_i C_i(y)$, where $C_i(y)$ is the marginal cost with respect to the output component y_i). For the public transport case, the definition implies that all the passenger flows increase by the same factor. Economies of scale imply decreasing ray average cost, which reduces to the familiar idea of declining average costs in the case of a single output ([Panzar and Willig, 1977](#)). In the case of public transport, decreasing ray average costs mean only that equiproportionate division of the passenger flow vector into two or more firms would increase system costs. If the division of passenger flows is not equiproportional, there is no warranty that the system costs increase. Therefore, the degree of economies of scale measures a specific effect of output increment on the costs, which is the effect of the division of passenger flows between two or more firms keeping the same distribution of flows across the origin-destination pairs.

The economies of scope relate the effect of divide the form's output vector in two or more firms with output vectors are a partition of the original vector. To define economies of scope formally, we consider a partition of the output vector. If $N = \{1, \dots, n\}$, then a partition of N is a set $T = \{T_1, \dots, T_J\}$ such that T_j is a subset of N , for all j , the union of all T_j s forms the set N , the intersection of T_j and T_k is empty, for all $j \neq k$, and $J > 1$. We denote y_{T_j} the n vector whose elements are set equal to those of y for i in T_j and 0 otherwise. Then, there are economies of scope for the partition T if $\sum_{j=1}^J C(y_{T_j}) > C(y)$ ([Panzar and Willig, 1981](#)).

For instance, in the case of the vector of passenger flows $y = (y_1, \dots, y_{20})$, a partition would be $T_1 = \{1, \dots, 10\}$ and $T_2 = \{11, \dots, 20\}$, and the vectors from this partition would be $y_{T_1} = (y_1, \dots, y_{10}, 0, \dots, 0)$ and $y_{T_2} = (0, \dots, 0, y_{11}, \dots, y_{20})$. It is worth noticing that even if the partition is theoretically admissible, in the case of a bus line, it could imply that the passengers may alight in some stops (zones) but not board or vice versa because of the origin-destination structure of the demand.

The concept of economies of scope is useful to analyze the convenience of expanding the spatial scope of the public transport firm. For instance, consider a new bus line composed by the original bus line that connects five zones but now connecting a new zone. To analyze the economies of scope, we need to compute three costs: the new bus line connecting the six zones, whose output vector has 30 components, the original bus lines with an output of 20 components, and the costs of providing public transport between the added zone and every original zone (10 components). The latter costs correspond to the extra components of the output vector needed to form a partition of the output vector from the bus line connecting the six zones. Then, there exist economies of scope if the new line's costs are less than the sum of the original bus line's costs and the costs of providing service for the extra components of output (in the most efficient way). It is worth noticing that, when applying the formal definition of economies of scope to public transport, the way to define output vector partitions is limited by the physical and operational configuration of the public transport network.

The previous definitions of economies of scale and scope need a cost function specified with disaggregate output. As explained, usually, there are not enough data to estimate such a cost function and the solution is the use of aggregate output. This solution imposes some constraints in the analysis of industrial structure because of the impossibility of computing ray average costs and defining partitions for the output vector.

So, when using aggregate output, [Small and Verhoef \(2007\)](#) point out the importance of retaining the distinction between expanding the density and expanding the spatial scale of output. The expansion of density implies keeping constant the spatial scope of the firm (e.g., route network or the number of served points) while the aggregate measure of output (e.g., passengers or passenger-kilometers) increases. If the average cost decreases when density expands, the industry exhibits economies of density. When using a demand-oriented aggregate output, the economies of density are equivalent to the multi-product economies of scale concerning the disaggregate output vector ([Jara-Díaz, 2007](#)).

The expansion of the spatial scale involves new components of the disaggregate output vector because expanding the network implies, for instance, supplying service between new origin-destination pairs. Strictly speaking, this is an expansion of scope (number of products) and must be analyzed as economies of scope ([Panzar and Willig, 1981](#)). However, when using aggregate output, the separation between scope and scale is difficult, if not impossible. Regarding this inseparability, [Small and Verhoef \(2007\)](#) say the industry exhibits economies of size when network expansion, along with aggregate output expansion, reduces the average cost. It is worth noticing that the concept of economies of size, which are usually called economies of scale in transport literature, is ambiguous because it implies new origin-destination pairs served and output expansion.

Moreover, the level of scale economies depends on the selected output regarding the supply-oriented output versus the demand-oriented one. For instance, some studies find scale diseconomies in terms of supply-related output, whereas they noticed economies of scale in terms of demand-related output. When comparing demand-oriented and supply-oriented scale economies, there seem to be higher returns to scale with demand-oriented outputs (trips, journeys, receipts per passenger, or passenger-kilometers) than with supply-oriented outputs (vehicle-kilometers or seats-kilometers) ([Croissant et al., 2013](#)). These results are also consistent with the idea that an additional passenger increases the cost very little if the supply does not increase (for instance, [Batarce and Galilea, 2018](#)). It is worth noticing, however, that the level of economies of scale depends on the selected output, control variables for heterogeneity and functional form of the cost function.

Efficiency, Contracts, and Regulation

Finally, a relevant topic in the analysis of operating costs of public transportation is the measurement of efficiency and the effects of regulation and procurement contracts on it. A standard method to measure efficiency is the stochastic frontier analysis ([Kumbhakar and Lovell, 2003](#)). This method assumes that the firms' inefficiency is a specific, unobservable component of the firm's production technology. This unobservable component is modeled as a random variable independent across firms, and its distribution is used to measure the firms' efficiency level. In transportation literature, most studies estimate the determinants of the efficiency of the firm and the level of subsidy. For instance, some authors estimate stochastic frontier models and study the mean inefficiency as a function of the type of contract, ownership regime, or subsidization mechanisms.

The results show that technical efficiency is not independent of the institutional or regulatory constraints. For instance, private operators outperform public ones in terms of efficiency ([Roy and Yvrande-Billon, 2007](#)), operators under cost-plus contracts exhibit a higher level of technical inefficiency than operators under fixed-price contracts ([Gagnepain and Ivaldi, 2002](#); [Piacenza, 2006](#)), and high-powered scheme of regulation, such as yardstick competition, significantly reduces operating costs ([Dalen and Gómez-Lobo, 2003](#)).

History

The concept of natural monopoly appeared with [Smith \(1776\)](#) who, without naming it, explicitly provided the main characteristics of what scholars after him refer to as “natural monopoly.” Its definition has then evolved through time and has attracted the attention of several famous scholars of the 17th–18th centuries, such as Thomas Malthus, Frédéric Bastiat, John Stuart Mill, and Léon Walras.^a

In the earliest explicit use of the concept, natural monopolies referred to as monopolies derived from natural factors of production, which are supplied in fixed quantity, with the idea that the limited supply of such factors constitutes barriers to entry.^b The first definition, however, was given by J.S. Mill: natural monopolies were “those which are created by circumstances, and not by law.” At that time, natural monopolies were therefore those created by nature, due to the presence of production factors supplied in given, and potentially limited, quantity; *natural monopolies* were thus distinguished from *artificial monopolies* created by law, that is, by government measures. For Mill, natural monopolies encompassed many situations, including, for instance, barriers to entry due to capital requirement. Mill was also the first to recognize that natural monopolies could arise due to the production process, that is, due to technological reasons.

Afterwards, natural monopolies were meant to arise due to the presence of economies of scale, that is, when the average total cost is decreasing. This happens, in particular, when there are fixed (potentially sunk) costs and low or zero marginal costs. In this situation, the cost of the incumbent firm is lower than the cost of any other firm that would wish to enter the market, and, in turn, that firm remains alone in the market. Then, price is not equal to the marginal cost, as in the case of perfect competition, since profit maximization requires the monopoly to equalize marginal revenue to marginal cost; and the monopoly produces too little with respect to the social optimum conditions, so that the government may wish to regulate it.

The current formal definition used in the academic literature is due to [Baumol \(1977\)](#) and is closely related to the subadditivity of the cost functions, that is, natural monopolies arise when the production cost associated to any set of outputs is less than the sum of the costs of producing separately all the different products in this set of outputs (see the formal definition later).

Very soon, academic scholars recognized that monopolies were unavoidable in transport networks, such as railways, roads, and highways. For Jules Dupuit, a French engineer, monopolies in transport networks are due to their need to build a large infrastructure before operations could start. This makes the entry of a new firm impossible because only a very limited number of entrepreneurs can have access to a sufficiently huge capital. Moreover, if a new firm entered the market, it would extract profits from the incumbent monopoly, making both of them unprofitable. By contrast, for Walras, monopolies arise because only the government can decide the expropriation of the lands required to build the transport networks. Note also that, in transport networks, the presence of several small businesses is inefficient: as highlighted by [Walras \(1936\)](#), “building a second network of roads in a country where there is already one that is enough for all the communications would be an absurd way of chasing economies.”

However, many monopolies we know remain unchallenged given that strong regulations often protect them. Productions of electricity, of nuclear weapons, and of military defence involve large fixed cost, and have been (and are still, for since several decades) protected by governments. By contrast, several economists belonging to the Austrian School such as Ludwig von Mises or Friedrich von Hayek have advocated that natural monopolies do not really exist (Thomas J. DiLorenzo speaks about “myth of natural monopolies”) but are often the outcome of regulation or of some kind of State protection. The libertinism of the Austrian School is here a bit confusing. What is true, for sure, is that governments often play a role in protecting some natural monopolies. However, other monopolies, even “natural,” could be challenged by firms using improved technologies.^c

^a See [Mosca \(2008\)](#) for an excellent history of the concept of natural monopoly.

^b In 1815, Malthus, in his essay *The Nature of Rent*, made the distinction between “natural” monopoly and “artificial” monopoly. For instance, he mentioned as natural monopoly the case of “certain vineyards in France, which, from the peculiarity of their soil and situation, exclusively yield wine of a certain flavour.”

^c Entry in the taxi market, for example, has been historically difficult in France, especially in Paris, Île-de-France; but Uber managed to break (more or less successfully) this market in December 2011, see https://en.wikipedia.org/wiki/Timeline_of_Uber, and started to capture customers, even when facing low network externalities, because they developed a revolutionary technology and were prepared to face (at least initially) negative profits.

Formal Definition of the Natural Monopoly

A monopoly is a market structure in which a single firm produces a good or service without any close substitutes. Monopolies may have several sources, such as legal barriers (e.g., patents), capital requirements, economies of scales, etc. One particular form of monopoly is the natural monopoly, which arises when a single firm is able to offer that good or service to an entire market at a lower cost than two or more firms could. This means that a natural monopoly can be the outcome of an unrestricted competition.

The current formal definition of the natural monopoly is due to Baumol (1977) and is closely linked to the strict subadditivity of the cost function. A cost function $C(y)$ is *strictly subadditive* if, for any vector, $(y_1, \dots, y_M)$:

$$C\left(\sum_{m=1}^M y_m\right) < \sum_{m=1}^M C(y_m),$$

where the quantities y_m are either quantities of different outputs or different quantities of the same output. A necessary and sufficient condition for a natural monopoly to exist is that the cost function is subadditive, which means that a single firm could produce at a cheaper cost compared to several firms.

The definition is also related to the concepts of economies of scale and economies of scope, which are cost efficiencies formed by quantity and by variety, respectively. *Economies of scale* correspond to a decreasing average total cost, while *economies of scope* arise when it is cheaper to produce several products together than to produce them separately.

For single product cost functions, economies of scale and economies of scope are sufficient but not necessary for subadditivity. This means that a natural monopoly arises when there are economies of scale or economies of scope over the relevant range of output (i.e., the range of output between the first unit of output produced and the output which consumers would demand at a zero price). For multiproduct cost functions, however, these conditions are neither necessary nor sufficient.^d

The subadditivity of the cost function is also related but must be put in perspective with the concept of sustainability of monopoly, which refers to “[a]n industry to which entrants are not ‘naturally’ attracted, and are incapable of survival even in the absence of ‘predatory’ measures by the monopolist” (Baumol, 1977). In particular, Faulhaber (1975) shows that subadditivity of the cost function does not imply sustainability of the monopoly, while Baumol et al. (1977) show the converse.

To illustrate what happens, consider a monopoly that produces and sells a single good or service at single price (i.e., absent of price discrimination). The monopoly produces a quantity y so as to maximize its profits $\pi(y)$ defined by the difference between its total revenues $R(y)$ and its total costs $C(y)$:

$$\pi(y) = R(y) - C(y) = p(y)y - C(y),$$

where $p(y)$ is the (decreasing) inverse demand function, which gives the price at which the quantity y can be sold.

Assuming that price and cost are differentiable and well behaved, profits will be maximum when marginal revenues equal marginal costs, that is, when $R'(y) = C'(y)$.^e Since total revenues are equal to price multiplied by demand, this first-order condition leads to the monopoly pricing formula, also known as the inverse elasticity rule:

$$\frac{p(y) - C'(y)}{C'(y)} = -\frac{1}{\varepsilon},$$

where $\varepsilon = \frac{p'(y)}{p(y)/y}$ represents the elasticity of demand. The right-hand side of the earlier equation is referred to as the Lerner index and measures the market power of the monopoly.^f

As illustrated in the top panel of Fig. 1, where marginal costs are assumed to be constant, profits are maximum at the point of intersection denoted by E , where the monopolist produces a quantity y_m and sells at a price p_m .

At this optimum, the monopoly obtains profits equal to π_m and consumers enjoy a surplus of CS_m . The society incurs a deadweight loss of DL_m : the social surplus, equal to $\pi_m + CS_m$, is lower than its socially efficient level (obtained under perfect competition), since the monopoly sets a price strictly higher than marginal cost.

For the natural monopoly, the situation gets more complicated. This is because the natural monopoly typically exhibits a decreasing total average cost, which implies that its marginal cost is lower than its average total cost. This situation is illustrated in the bottom panel of Fig. 1 for a firm with (large) fixed costs and (low or zero) constant marginal costs. In this case, the monopoly serves the entire market at a lower cost than multiple firms could achieve. For the natural monopoly, profits are still maximum at the point of intersection denoted by E , which is, however, the most undesirable situation for the society since it leads to high prices, small outputs, and a large welfare loss.

^d Consider, for example, the multiproduct cost function, when there are two outputs, 1 and 2:

$$C(y_1, y_2) = y_1 + y_2 + (y_1 y_2)^{1/3}.$$

Clearly, this cost function exhibits economies of scale when productions are strictly positive, but is never subadditive.

^e The maximum is attained provided that the second-order condition of the profit maximization program is satisfied.

^f The Lerner index is a measure of monopoly power since the higher its value, the more the firm is able to charge over its marginal cost. Lerner index ranges from 0 to 1. It cannot be negative under the assumption that negative profits are ruled out; and it cannot exceed one under profit maximization. In particular, it is equal to 0 in perfect competition where price equals marginal cost.

Figure 1 Monopoly and natural monopoly.

Regulating a Natural Monopoly

The inefficiency of the (natural) monopoly justifies its regulation, which aims to reduce its price and therefore increase its output. To address the inherent inefficient behavior of the monopoly, policymakers or governments can resort to regulation or public ownership (i.e., in the limiting case, they can decide to run the monopoly themselves, that is, opt for nationalization).

The choice of the regulated price is not easy. The government may want to set the price equal to the monopoly's marginal cost (marginal-cost pricing), so that efficiency is restored. However, this regulatory scheme faces two drawbacks.

First, the monopoly facing the marginal-cost pricing policy would incur losses and may, in turn, exit the market, since this policy leads to a price lower than average total cost (marginal cost being lower than average total cost). The government can address this problem, for example, by subsidizing the monopoly. However, in this case, the government incurs the loss, which can be covered by a tax that is associated itself to a deadweight loss. Alternatively, the government can allow a price higher than the marginal cost, for example, by choosing an average-cost pricing rule so that the monopoly just makes zero profit, which is associated to a lower deadweight loss.

Second, marginal-cost pricing does not provide the monopoly the incentives to reduce its costs. In a competitive market, firms can make higher profits by reducing their costs. By contrast, with the marginal-cost pricing rule, the regulated monopoly will not obtain higher profits by reducing its costs. The government can address this problem by designing a contract to induce the monopoly to reduce its cost as much as possible. Such incentives schemes are not simple to implement since effort of the monopoly is not directly observable.

To be more specific, consider the regulation of a monopoly producing M goods or services, indexed $m = 1, \dots, M$, when regulated prices are linear.⁸ In the Ramsey–Boiteux problem, the social surplus is maximized under the constraint that the firm (here the monopoly) breaks even. Let $S(y)$ denote the surplus that consumers derive from purchasing a vector of quantities $y = (y_1, \dots, y_M)$. The government solves:

$$\begin{aligned} \max_y \{ & S(y) - C(y) \} \\ \text{s.t. } & R(Y) - C(y) \geq 0, \end{aligned}$$

⁸ Linear prices are unit prices that are constant for each product and that therefore depend neither on the quantity sold (no second-degree price discrimination, involved, for example, in quantity discount), nor on the identity of the customers (no third-degree price discrimination, where customers with different characteristics pay different prices for the same good or service).

where, as earlier, $R(y)$ is total revenues and $C(y)$ is total costs. First, consider the simple case in which demands for the products are independent. The first-order conditions lead to the Ramsey–Boiteux pricing:

$$\frac{p_m(y) - C_m(y_m)}{p_m(y)} = \frac{\lambda}{1 + \lambda} \frac{1}{\eta_m}, m = 1, \dots, M,$$

where η_m denotes the own-price elasticity of good or service m , p_m its price, and C_m its marginal cost, and where $\lambda > 0$, the Lagrange multiplier represents the shadow price of the budget constraint (or the shadow cost of public funds with government transfers).

Accordingly, for each good or service, its Lerner index is inversely proportional to its own-price elasticity. However, it should be noted that the Lerner index is smaller than the inverse elasticity of the demand since $\lambda > 0$, whereas, as seen earlier, in the unregulated monopoly, the Lerner index is just equal to its corresponding inverse own-price elasticity of demand.^b

In practice, the regulator sets a price cap at the beginning of each period. The regulated price in period 1, p_1 , is given by:

$$p_1 = p_0(1 + \text{RPI} - X),$$

where p_0 is the regulated price in period 0, Retail Prices Index (RPI) is the inflation rate, and X is the *efficiency factor* (i.e., the expected efficiency improvements).ⁱ One period is typically between 3 and 5 years. The RPI can be measured by the Consumer Price Index—or RPI as used in the United Kingdom.^j The evaluation of X is trickier, since it depends on the evolution of the inputs price and on the expected change in productivity. In practice, the regulator resorts to some heuristic rules, rather than to a full econometric analysis, which may be hard to accomplish. Benchmarking is another alternative, although studies may not always be comparable, so that econometric analysis is required.

For example, Gagnepain and Ivaldi (2002) examine the impact of incentives in the case of public transportation (buses) in France. They examine how incentive compatible contracts (à la J.-J. Laffont) may induce the bus companies to lower their costs, and compare two different regulator contracts, the *cost-plus contracts* (based on observed costs and *ex-post* deficits are covered) and *fixed price contracts* (based on expected costs and expected deficits). They empirically show that fixed price contracts are more efficient to reduce costs than cost-plus contracts.

This study shed useful light on the importance of incentives in the design of the contracts. The efficiency of the contracts varies significantly according to the size of the network, the density of the customers, and the geographical characteristics. This is a common trait to many studies in transportation areas, such as airline, maritime, railroads, rail freights, or highways. Much work remains to be done to better understand the best way to regulate monopolies.

We cannot close this section without alluding to the fact that regulation may potentially reduce product innovation and process innovations. Lastly, note, as shown by Deneckere et al. (2019), that risk aversion of the principal (here the government) and the agent (here the monopoly) changes significantly the optimal contracts.

Econometrics of Natural Monopoly

With data on costs and input at hand, the cost function can be estimated to determine whether it is subadditive or not, that is, whether the industry under consideration is a natural monopoly or not. However, subadditivity is difficult to verify empirically. Fortunately, for the multiproduct case, a sufficient condition for the cost function to be subadditive is that its second partial derivatives are not positive over the relevant range of output. This condition, called “cost complementarity,” means that an increase in the production y_i of good or service i decreases the incremental cost of producing the quantity y_j of good or service j .

Cost complementarity may be hard to test empirically over the relevant range of output, but can easily be tested at the data point. Then, from an econometric point of view, we are interested in local conditions:

$$\frac{\partial^2 C}{\partial y_i \partial y_j} < 0.$$

The first step consists in assuming a functional form for the cost function that is able to identify whether or not there are cost complementarities. Flexible functional forms are usually used.^k For example, Foreman-Peck (1987) uses the generalized translog (GTL) multiproduct cost function to estimate the cost function of the British railways.

^bThis analysis can be extended to the case where products are not independent. If they are substitutes, the Ramsey–Boiteux prices are higher; if they are complements, prices are lower.

ⁱFor a discussion on how to measure efficiency, see Gagnepain and Ivaldi (2002).

^jSee http://oa.upm.es/43724/1/Mariana_Rodrigues_Brochado.pdf.

^kThe flexible functional form was introduced by Diewert (1974). A flexible cost function is able to approximate an arbitrary twice continuously differentiable cost function to the second order at the data point. This is the reason for which only a local measure of cost complementarity may be tested. See Diewert (1974) and the literature that follows for more details and for other examples of flexible functional forms.

The GTL multiproduct cost function model is defined as follows:

$$\ln CY(w) = \alpha_0 + \sum_{i=1}^N \alpha_i \ln(w_i) + \sum_{i=1}^M \beta_i Y_i + \frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N \alpha_{ij} \ln(w_i) \ln(w_j) + \frac{1}{2} \sum_{i=1}^M \sum_{j=1}^M \beta_{ij} Y_i Y_j + \sum_{i=1}^N \sum_{j=1}^M \rho_{ij} Y_j \ln(w_i) + \varepsilon,$$

where $w = (w_1, \dots, w_N)$ denotes the price vector of the N inputs, $Y = (Y^{\lambda_k} - 1)/\lambda_k$ denotes the Box-Cox transformation of the output vector of the M goods or services $y = (y_1, \dots, y_M)$, ε denotes the error term of the model, and the α s, the β s, and the γ s are parameters to be estimated.¹

Given the large number of parameters to be estimated, the statistical precision of parameter estimates can be improved by assuming that firms minimize their (input) costs to produce the exogenously predetermined levels of output. In turn, Shephard's lemma can be applied to the cost function C in order to obtain the following cost share equations:

$$S_i = \alpha_i + \sum_{j=1}^N \alpha_{ij} \ln(w_j) + \sum_{j=1}^M \rho_{ij} Y_j + \varepsilon_i, i = 1, \dots, N,$$

where ε_i denotes the error term of the model.^m The cost function can then be jointly estimated with $N - 1$ of the N share equations by using the method developed by Zellner (1962) for estimating seemingly unrelated regression models.

For the GTL multiproduct cost function model, the local cost complementarity is given by:

$$\frac{\partial^2 C}{\partial y_i \partial y_j} = \frac{C}{y_i y_j} \left[\frac{\partial \ln C}{\partial \ln y_i} \frac{\partial \ln C}{\partial \ln y_j} + \beta_{ij} y_i^{\lambda_i} y_j^{\lambda_j} \right],$$

which can be computed after estimation.

This methodology was used by Foreman-Peck (1987), to study the cost-structure of the railway industry in the United Kingdom during the 19th century in order to fuel the discussion of the efficiency of private versus public ownership.

Natural Monopolies in Transports: Panorama and Case Study

In transport, natural monopolies are important phenomena and arise, amongst other reasons, because the transport sector is capital intensive and needs large infrastructure to start producing. However, once fixed costs have been covered, the marginal cost to provide an extra unit of service is typically low. Since fixed costs are sunk, if an incumbent firm wishes to enter the market, the existing firm can easily cut prices to protect its market. On the other hand, if learning by doing is important, the incumbent firm may benefit from lower costs. Moreover, the incumbent firm can scream the market and serve the most profitable customers. For example, the intercity railways are more profitable than the regional railways, where demand is sparser.

With the opening of the market in the railway market in France (December 2019 for local train and December 2020 for intercity train), it is likely that the non-French competitors will first enter the most profitable niches. However, practice is somewhat different. It should be noted that the First European Railway Directive, which dates back to 1991, allowed open access for passengers and freight trains. In 2019, still not much competition occurs. Breaking State monopoly is in the agenda, but political and institutional barriers still remain very strong. The study of natural monopolies should not ignore their most important facet: the political economy dimension, such as electoral competition, centralized versus decentralized decisions, etc. Deregulation has been so far more successful in the airline industry or in the truck industry, even if several imperfections remain, as widely discussed by Joskow (2007).

The case of the British railways in the 19th century provides an interesting case study (Foreman-Peck, 1987). Competition has virtue to lower the price, while possibly leading to either duplication or underutilization of tracks. Moreover, competing firms may deny and make difficult interconnections. The Railway Clearing House, created in 1947, encouraged interconnection and fair competition. The estimations of Foreman-Peck (1987) suggest that before regulation, construction costs were 50% higher and national income per capita 0.75% lower than if would have been in a properly regulated market.ⁿ History teaches us that nationalization does not solve all problems. In 1911, the British railways were heavily regulated, yet the performance was poor

¹The GTL function of cost generalizes the translog function of cost by using the Box-Cox transformation, rather than the logarithm, for the output levels. It therefore allows to include zero outputs. The Box-Cox transformation reduces to the logarithm as λ_k approaches zero.

^mNote also that linear homogeneity (in input prices) of the cost function and symmetry of its Hessian matrix can be imposed by using the following linear restrictions on parameters:

$$\sum_{i=1}^N \alpha_i = 1, \sum_{j=1}^N \alpha_{ij} = 0, \sum_{j=1}^M \rho_{ij} = 0, \alpha_{ij} = \alpha_{ji}, \beta_{ij} = \beta_{ji}.$$

ⁿInterestingly, he says that in "1856 Belgian third class fares per miles were one quarter lower than the British fare and in 1883 40% less, while freight was similarly cheaper."

since competition was absent. However, privatization of British Rail, 20 years ago, was not a full success either, with high fares, low reliability, and little customer's support.^o

The study of natural monopoly is by far not completed and raises questions opened for deep debates. Possibly, the divorce of ownership and control may provide a solution to a problem that seems to never end.^p

Acknowledgment

We would like to thank Maria Börjesson for her useful comments and suggestions, as well as for her kind replies to our questions.

Introduction

A freight cost function is a mathematical formula which expresses the total cost of moving and/or handling freight as a function of some major influential factors, such as the amount of freight shipped, line-haul (trip or voyage) distance, network size, etc. Freight cost functions can be established to express either the cost of a single trip (or voyage) or the cost borne by a freight shipping company, such as all-cargo airlines and container shipping lines, over a period of time. This chapter focuses on freight cost functions of two transport modes, air and shipping. The reason of discussing these two modes of transport in one chapter is that both modes share lots of similarity in cost structures while at the same time each possesses some special features.

Before understanding how major factors associate with freight costs, one must understand the cost components of each mode of transport. Although capital, labor, and energy are the main inputs of providing transportation services, this classification does not associate costs with various key operations and activities and provides limited managerial insights. Thus, in Section, "Freight Cost Components: Air Versus Sea," costs are classified based on their associated functions, such as line-haul operation (flying the airplanes or sailing the ships) and ground handling/terminal operation, etc. Section, "Key Influential Factors of Costs" explains how several key influential factors affect costs in air freight transport and shipping, respectively. Trip (voyage) cost functions are presented in Section, "Trip (Voyage) Cost Functions." In Section, "Company-Level Cost Functions," company-level cost functions are discussed as well as the economies of scale and density. Section, "Conclusion" concludes this chapter.

Freight Cost Components: Air Versus Sea

There are different ways to classify costs. A common method in the economics literature is to divide the total cost into fixed and variable costs. Costs related to the fleet, equipment, and overhead are usually considered as fixed while those related to labor and energy and providers of ground handling services are usually considered as variable. On the voyage basis, in the shipping literature, capital costs of owning vessels, including the costs of ships and related financing costs, are separately listed in addition to fixed and variable costs. As a result, fixed costs only include costs paid to maintain the ships in navigable conditions and the fixed port charges. However, whether an input is fixed or variable depends on the time horizon and the type of decisions to be made. In a fleet planning scenario, fleet cost is obviously variable, but if one only investigates a particular flight or voyage with a given airplane or ship, many inputs can be fixed, even for certain part of the labor and fuel as well as airport/terminal charges. Thus, such discussion has to be grounded on specific cases and is not the focus of this chapter.

In terms of functions, air and sea shipping share lots of commonalities. According to [Table 1](#), both include three major aspects with different terms but similar meanings, that is, line-haul activities, terminal activities, and system operating activities. In the context of air transport, both ground handling and system operating costs are considered as indirect costs since they do not directly associate with operating the flights while flight operation costs are also called "direct operating costs" (DOC). Various organizations have somewhat different standards when asking airlines to report their costs, but the main ideas are similar. One major difference between these two modes comes from the treatment of airport/port charges. Airport charges levied on aircraft (i.e., landing/take-off and parking charges) are considered as terminal costs while port charges levied on ships are considered as ship (line-haul) costs [Stopford \(2009\)](#). Port charges include pilotage, mooring/unmooring fees, wharfage, towage, tonnage dues, light dues, port state, pollution control fees, etc.

Table 1 Function-based cost components

Functional areas	Air	Sea
Line-haul	Flight operation costs: costs associate with owning, renting, maintaining, and flying the aircraft. Fuel and flight crew (pilots) costs are also included.	Ship costs: ship capital and financing costs, crew costs, ship repair and maintenance costs, bunker costs, port costs
Terminal	Ground handling costs: costs associate with servicing aircraft, landing/parking aircraft at the airports, loading/unloading/processing cargo at airport terminals, as well as sales and promotion	Terminal and cargo costs: terminal costs for handling/storing containers, costs associate with maintaining and supplying containers, agency costs
System operating	Costs associate with administration, overheads, customer services, and other transport-related, such as services offered by partner airlines	Administration/overhead costs, inland transport costs, ship repositioning costs

In addition to cost items listed in **Table 1**, special cost items need to be added when ships are operated on certain routes. When the ships pass through canals, there incurs canal fees and the impact of congestion on cost should be taken into account. The costs for safety equipment and guards should be added if ships transit in zones with high risk of piracy attacks. Ice-breaking fees are sometimes required for voyages through the Arctic Ocean.

Based on the standard of US Department of Transport (DOT), **Table 2** shows cost decomposition of selected US-based cargo airlines and passenger airlines in 2017. **Table 2** compares cost decomposition of three groups of airlines: FedEx, the other three major cargo airlines in the United States, namely Atlas Air, Polar Air Cargo Airways, United Parcel Service (UPS), and selected major passenger airlines, including Alaska Airlines, American Airlines, Delta Air Lines, Envoy Air, Frontier Airlines, Hawaiian Airlines, Southwest Airlines, Spirit Air Lines, United Air Lines, and Virgin America. FedEx is separately reported, because it counts costs of ground operating/trucking services provided by its “sister” companies into transport-related costs, which is broadly defined as expenses applicable to the generation of transport-related revenues. However, the other three cargo airlines assign costs of subcontracted ground/trucking services into individual cost components based on the nature of subcontracted services instead of bundling them into transport-related costs (Onghena, 2011). This different treatment causes FedEx an unusually low share flight operation costs (21.77% compared with 82.01% of the other cargo airlines) and an unusually high share of transport-related cost (57.78% compared with 0.30% of the other cargo airlines). As a result, FedEx cost structure is very similar to passenger airlines as mainline passenger airlines rely a lot on regional airlines to provide feeding services of which the expenses are also counted in transport-related costs. However, taking transport-related costs out of the picture, one can still conclude that flight operating costs account for majority of a cargo airlines’ total operation costs of which fuel and oil, flight equipment maintenance and flight crew are the top three largest cost components. In addition, aircraft and traffic serving costs account for another large trunk.

Table 3 provides an example of cost shares of a typical voyage of a container liner service. Costs associated with ships account for 37%–54% of total costs. After excluding port costs, about 33%–47% of the total voyage costs associate with line-haul activities. This number is similar to air freight transportation. Terminal and container costs account for another 19%–26%. Since seaports are located far away from inland regions, inland intermodal transport accounts for a trunk share (17%–23%) of total container shipping

Table 2 Decomposition of total operating cost of selected US-based cargo airlines in 2017

Cost category	FedEx	Other selected cargo airlines	Selected passenger airlines
Fuel and oil	6.17%	28.16%	17.43%
Maintenance–flight equipment	6.29%	18.16%	8.81%
Flight crew	4.79%	17.22%	11.78%
Rentals and insurance–flight equipment	1.69%	11.79%	2.71%

costs. The other top three cost components are bunker, ship capital, and container handling costs. The cost structure is very consistent across ship sizes, while larger ships tend to have smaller share of line-haul costs and larger share of terminal handling and inland transport costs.

Key Influential Factors of Costs

Prices of various inputs, such as crew wage rate, jet fuel, or bunker prices and prices of aircraft or ships, affect cost of freight operation. Pilot wage rate can vary significantly across countries, seniority, and airlines. Sea-going crew wage is related to the nationality of the crew, which is linked to the registration of ships. Jet fuel and bunker prices may also vary across locations and of course are affected by various external shocks mainly out of the control of freight operators. Prices of aircraft tend to be high for newly developed models and new aircraft. Old aircraft are much cheaper due to most likely lower fuel efficiency and higher maintenance costs. Prices of ships are related to the type, size, and design of the ship as well as the freight rate in the market. Given that it is almost impossible to have a clear and concise discussion on the dynamics of these input prices, our focus is on operational characteristics, which influence freight operation costs, or more precisely productivity.

Non-Price Factors of Costs: Air Freight

Direct operating costs can substantially vary across aircraft models. Cost per block hour, cost per available ton-km (ATK), and cost per revenue ton-km (RTK) are widely used to compare the costs of operating different aircrafts in different context ([Morrel, 2011](#)). Cost per block hour tells the costs of having an aircraft in use by one hour. Roughly speaking, the counting of block hour of a flight cycle starts when the aircraft leaves the gate for departure and ends when the aircraft arrives at the gate of the destination terminal. Cost per ATK and cost per RTK are usually considered as unit cost, since they not only divide the cost by the distance flown but also the amount of available cargo carrying capacity (for ATK) and the amount of actual cargo carried (for RTK), while cost per block hour does not assign costs to each ton of cargo. [Table 4](#) presents DOC per block hour, DOC per ATK and DOC per RTK of some representative freighters, that is, all-cargo aircraft, based on data reported by FedEx and UPS. In addition, [Table 4](#) also lists some major influential factors of DOC, such as average payload, average stage length (i.e., distance per flight segment), and block hours per day.

In general, for the same aircraft model, cost per block hour is highly affected by block hours per day. For example, the DOC per block hour of UPS' A300-600 is much lower than the same aircraft model of FedEx, while the block hour per day of the former is 1.59 hours more than the latter. Block hours per day tells the number of hours on average an aircraft is in use and hence it reflects aircraft utilization, that is, high block hours per day means high aircraft utilization. While the aircraft capital costs (i.e., depreciation and rentals) are associated with the time that the aircraft is owned and rented by the airline, the generation of freight transport services is linked to the time that the aircraft is in use. Note that although in a typical aircraft leasing agreement, the lessee pays for each block hour, there is usually a minimum block hour limits that the lessee must pay for. Therefore, as the utilization of an aircraft increases, its capital costs can be spread over more block hours, leading to lower cost per block hour. This can be seen by comparing the sums of depreciation and rental costs of B767-300. Although for this model FedEx has lower DOC per block hour than UPS, which might be caused by FedEx's outsourcing of maintenance costs, the sum of hourly depreciation and rental costs is still lower for UPS, which achieves higher block hours per day.

Unit costs:											
DOC per ATK (US cents)	458	527	167	322	410	222	124	177	225	151	196
DOC per RTK (US cents)	815	1,020	279	553	887	338	216	364	410	217	311

Note: Payload equals to the certificated takeoff weight of an aircraft, less the empty weight, less all justifiable aircraft equipment, and less the operating load (consisting of minimum fuel load, oil, flight crew, Steward's supplies, etc.)

Source: Data from US DOT Form 41.

The average stage length also relates to costs. On one hand, aircraft utilization might be improved by flying a longer distance, as making a stop takes lots of time and longer flying distance means that fewer stops will be made during a given period of time. On the other hand, given an aircraft model, although longer flight distance suggests more fuel consumption during the cruise and more payment to flight crew, some costs are relatively independent of flight distance, such as fuel consumption during the taxiing, takeoff and landing stages, flight cycle-driven maintenance, as well as various handling and servicing costs incurred at the terminals. As a result, the costs of moving freight by one kilometer decreases as the average stage length increases, leading to a decrease in DOC per ATK and DOC per RTK. This can be seen by comparing the unit costs of MD-11: with a longer average stage length, UPS incurs lower unit costs even though its average available payload is lower than FedEx. However, according to the range-payload tradeoff, for any given aircraft type, once a certain distance is reached, further increasing stage length requires a reduction of the aircraft's freight carrying capacity (i.e., payload capacity). This is because to fly a longer distance, more fuel has to be carried on board, and as a result less freight can be carried to make sure that the aircraft does not exceed the maximum takeoff weight. Therefore, increasing stage length far above the most efficient range may lead to an increase in unit costs.

Aircraft size, or more accurately aircraft carrying capacity is another influential factor. As a large portion of a flight trip's costs is independent of the carrying capacity or the actual amount of freight carried. For example, the crew size is almost fixed regardless the size of the aircraft. Aircraft maintenance costs are affected by aircraft size, but not in a linear way. This feature is called economies of scale by some researchers while others call this economies of aircraft size or economies of traffic density, since scale in many contexts also refers to the production scale of an airline, which will be mentioned later. From [Table 4](#), one can easily observe that in general aircraft with larger average payload incurs lower DOC per ATK or DOC per RTK. Of course, larger aircraft also tend to be operated in longer routes, and thus the impact of average stage length may jointly play a role here.

In addition to carrying capacity, load factor which tells the actual proportion of the capacity utilized to carry freight affects DOC per RTK. Although more fuel needs to be consumed as more weight is carried, the amount of fuel for lifting the aircraft itself without any payload can be spread over more tons of freight carried if the load factor increases, leading to lower DOC per RTK. Scheduled flights tend to have lower load factor than charter services. Note that although each aircraft has fixed volume-metric capacity (space available for freight), the payload (weight) capacity depends on flight distance, weather condition, and many other operational considerations, such as the weight of passengers and their baggage in the case passenger aircraft. While, fuel consumption mainly relates to the weight of the cargo rather than the space it takes, and unit costs are usually calculated based on the weight of the freight. Thus, the load factor based on the weight capacity is more relevant than the volume capacity.

The above discussion applies to freighters which are mainly operated by all-cargo airlines, integrators (i.e., air express airlines) and combination airlines that operate both freighters and passenger aircraft (for example, Lufthansa, Cathay Pacific Airways). Passenger airlines, which do not operate freighters, carry cargo in the belly hold of passenger aircraft. Costing of belly cargo operation depends on how to allocate the joint costs between passengers and cargo, such as basic fuel without payload, flight crew costs, aircraft capital costs, aircraft insurance and maintenance, as well as landing fees and navigation service charges. Most passenger airlines allocate all joint costs to the passenger side of the business and assign only the incremental costs incurred by cargo-specific operations, such as cargo sales and promotion, freight insurance and additional fuel due to carriage of cargo, to the cargo services. This leads to substantially lower freight unit costs than those incurred by freighters.

Non-Price Factors of Costs: Shipping

Unlike aircraft, ships vary substantially in sizes. The capacity of a mega container ship can be 10 times as much as the capacity of a feeder container ship. In general, maritime shipping enjoys a much stronger economies of ship size. [Table 5](#) compares the unit costs of a typical voyage by containership sizes and unit costs per year by bulk ship sizes. The ship size is measured in twenty-foot equivalent unit (TEU) for containerships and deadweight tons (DWT) for bulk shipping. The total voyage cost increases as ship size increases while cost per TEU or cost per DWT declines. As the demand for freight transport is directionally imbalanced, costs can be highly different in directions. For example, eastbound voyage tends to move more containers than westbound, and therefore on per TEU basis, eastbound incurs lower cost.

Table 5 Cost per TEU or per DWT by ship sizes

Containership size (TEU)	1,200	2,600	4,300	6,500	8,500
Total voyage cost (\$'000)	2,027	3,721	5,719	8,229	10,382
Cost per TEU eastbound leg (\$)	938	795	739	703	679

Figure 1 Major network structures of cargo airline or shipping lines.

Bunker (fuel) cost in shipping is inextricably linked to ship speed and load factor given a particular ship. It is roughly estimated that for a given ship, fuel consumption of a ship has a cubical (or exponential) relationship with the speed. Unlike aircraft, ships have a much larger room for speed changes. For example, the feasible speed of container ships may range from 12–15 knots (the lowest speed possible) to 20–25 knots (the designed optimal speed). Technically, reducing speed below this range will not bring any further reduction of fuel consumption; whilst, increasing speed above this range will lead to too much fuel consumption which is hardly compensated by reduced travel time. A 10%–20% speed cut (slow steaming) below the designed speed is very common when demand is low. To maintain stability, every ship has to reach a minimum displacement during the voyage and hence there is a minimum amount of fuel, which has to be consumed. When the load factor is below a threshold, cargo carried does not produce sufficient displacement and some ballast water has to be carried to reach the minimum displacement. As a result, the fuel consumption per unit of cargo will be increased, as cargo has to share the cost of carrying the ballast water. Once the threshold load factor is reached, although fuel consumption increases as displacement increases, ballast water is no longer needed and the fuel cost per unit of cargo will be reduced.

Shipping network also affects costs. Cargo airlines and maritime shipping companies mainly apply two network structures: circular (multi-port calling) network and hub-and-spoke network (Fig. 1). To satisfy the same shipping demand, circular network incurs higher ship costs than hub-and-spoke network mainly because the latter uses larger ships and requires fewer port calls and hence lower port costs (Imai et al., 2009). Sometimes ports can be highly congested, leading to the long waiting time and increased costs borne by carriers. However, the costs of terminal handling, feeding hub ports, and empty container management tends to be higher when hub-and-spoke network is used (Imai et al., 2009). This is caused by not only extra unloading and loading of containers at the hub for transshipment but also longer transit time and more handling of empty containers. That is, in highly directionally imbalanced trade routes, hub-and-spoke network is disadvantaged in terms of total costs.

Trip (Voyage) Cost Functions

Calculating a flight trip cost of an aircraft or a voyage cost of a ship is essential when making aircraft or vessel purchasing and deployment decisions. In practice, trip (voyage) cost function is estimated by adding up expenses of different freight transportation functions during a trip (voyage). These cost components are very similar for aviation and shipping (Table 6). The landing fees, navigation fees, and ground handling fees in aviation correspond to port charges and cargo handling fee in shipping.

Table 6 Cost components included in aviation (ATA, NASA, and AEA) and shipping

Table 7 Examples of trip and unit cost functions

Aircraft type	Trip cost	Unit cost
Passenger (Swan and Adler, 2006)	Short-haul single-aisle airplanes (1000 and 5000 km) $C = (D + 722) * (S + 104) * 0.019$ Long-haul twin-aisle airplanes, 2-class seating $C = (D + 2200) * (S + 211) * 0.0115$	Regional single-aisle airplanes $c = 2.44S^{-0.40}D^{-0.25}$ Long-haul twin-aisle airplanes $c = 0.64S^{-0.345}D^{-0.088}$
Any (Ali and Al-Shamma, 2014)	Trip cost based on designed stage length $C = -4.497 \times 10^{-7} \times MTOW^2$ $+ 0.9588 \times MTOW - 33214$	
Notations	C: aircraft trip cost; c: cost per seat kilometer; D: flight distance; S: seat count	

In air transport, three common methods are used to calculate the cost of a trip. They are proposed by the Air Transportation Association of America (ATA), National Aeronautics and Space Administration (NASA), and Association of European Airlines (AEA), respectively. The NASA and AEA methods include not only DOC but also some indirect cost items, but the ATA method only takes into account DOC (Air Transport Association of America, 1967) (Table 6). The trip cost is usually estimated as a function of various parameters, such as aircraft cost, airframe cost, engine cost, airframe weight, insurance rate, block hours of the flight, maximum takeoff weight (MTOW), etc.

As the costing procedure is complicated due to various details from the engineering perspectives, sometimes for higher-level strategic decisions, one needs a simpler way to link a trip costs with only a few key factors. This type of studies is rare for freighters, but there are studies for passenger aircraft. The upper part of Table 7 lists estimated functional forms of passenger flights' trip and unit costs. The resulting trip cost functions are functions of stage length and seat capacity. Similar idea can be applied to approximate trip cost of cargo flights by replacing seat capacity with payload capacity. Alternatively, a trip cost can be estimated based on MTOW and this method is valid for any aircraft type.

Cost functions listed in Table 7 well reflect the discussion in section "Key Influential Factors of Costs." While trip costs increase in flight distance (D) and aircraft size (S), unit cost is decreasing in stage length and aircraft size. In general, the speed of cost increase slows down as the MTOW increases. Therefore, twin-aisle (wide-body) aircraft, which are mainly operated in long-haul markets are likely to incur lower unit cost than single-aisle (narrow-body) aircraft operating in short-haul markets. Moreover, based on Table 7, one can also observe that in general single-aisle aircraft are more sensitive to aircraft size and flight distance than twin-aisle aircraft.

In sea shipping, we did not find any study which establishes a simple functional form linking voyage cost and one or two key factors. Rather, voyage cost is mainly expressed and evaluated as the sum of the detailed cost components based on certain assumptions.

Company-Level Cost Functions

As many cost items, especially indirect costs, are difficult to be assigned to a particular trip or voyage, it is sometimes relevant to understand at company level, how different factors influence the cost efficiency of a freight operator. Econometric models and regression analysis are widely used to achieve this objective. Costs of airlines or shipping companies are treated as the dependent variable and various factors are treated as independent variables to establish a functional form:

$$TC = f(Q, P, Z, F, N, T),$$

where TC is the total cost incurred by an operator, Q is the total output or traffic served by the operator, P is a set of input prices, Z is a set of operation-related factors, N is network size, F is a set of firm-specific unobservable characteristics captured by dummy variables, and T is a set of time-related variables. Total output and input prices are the fundamental part of these models, while other independent variables are added according to the issues studied and the specific features of the dataset.

The Cobb-Douglas function has been widely used in the model specification for cost estimations. When only output and prices of n inputs are taken into account, the total cost can be written in the following way:

$$TC = e^{a_0} Q^{\beta_Q} \prod_{i=1}^n p_i^{a_i}.$$

Then, a log transformation can be applied so that the following form is actually estimated statistically: $\ln TC = a_0 + \beta_Q \ln Q + \sum_{i=1}^n a_i \ln p_i$

This transformation makes it straightforward to identify the individual input's cost share among total cost. Differentiating both sides of the above equation with respect to $\ln p_i$ and applying Shephard's Lemma, one can show that the cost share of input i is exactly coefficient a_i . One can also easily obtain the elasticity of total cost with respect to output (ϵ_Q) as it is equivalent to coefficient β_Q .

Therefore, log-transformed Cobb-Douglas function is usually applied instead of Cobb-Douglas function itself. A more complicated specification is the general translog specification which uses a second-order Taylor expansion to approximate to the cost function. That is,

$$\ln TC = a_0 + \beta_Q \ln Q + \sum_{i=1}^n a_i \ln P_i + \frac{1}{2} \gamma_Q (\ln Q)^2 + \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \gamma_{ij} \ln P_i \ln P_j + \sum_{i=1}^n \delta_i \ln Q \ln P_i$$

where $\gamma_{ij} = \gamma_{ji}$, $\sum_{i=1}^n a_i = 1$, and $\sum_{i=1}^n \gamma_{ij} = \sum_{i=1}^n \delta_i = 0$. Similar to the log transformation of Cobb-Douglas function, one can easily obtain the cost share of each input by taking the partial derivative of the general translog function. In particular, $\frac{\partial \ln TC}{\partial \ln T_i}$ generates the cost share of input i , and the elasticity of total cost with respect to output will be

$$\epsilon_Q = \frac{\partial \ln TC}{\partial \ln Q} = \beta_Q + \sum_{i=1}^n \delta_i \ln P_i$$

In addition to output and input prices, the other control variables (Z , F , T) can be easily added into the equations with or without the log transformation, depending on the particular variable.

Variables Included in the Cost Function of Cargo Airlines

In air cargo transportation, both TC and variable cost (VC) have been used as dependent variables. Output is usually measured by total revenue ton-miles (RTM) total RTK of freight and mail. Four inputs' prices (P) are commonly considered: fuel, labor, material, and capital. In terms of vector Z , two operation-related variables are widely included: average stage length and load factor. The total number of airports served (N) is a key indicator of network size. Inclusion of network size is essential when one needs to measure and test the presence of economies of density and economies of scale for cargo airlines. As the difference between fixed and VC are relevant only when capital is fixed, when estimating VC , capital stock (K) is included as a control variable while price of capital is dropped. Capital stock can be measured by the asset value plus investment in flight equipment, ground equipment and property, capital leases, and land. After reviewing relevant studies in the literature, we list the studied cargo airlines, functional specifications, and variables in Table 8.

Variables Included in the Cost Function of Shipping Companies

Total cost, VC , and unit cost (UC) have been used as dependent variables in shipping. In bulk shipping, the output (Q) is measured in ton-miles. In container shipping, as the capacity of container ships is measured in TEU, the output (Q) is measured in TEU-miles transported by shipping lines. Different input prices (P) are used in estimations, including labor, fuel and oil, stores and materials, repairs and maintenance, capital stock, etc. Unlike air transport, size of the capital (K) is usually included and it is measured by the fleet capacity (Table 9). Some studies consider K as a control variable when estimating the functional form of VC of the short-run costs, while others include it even when estimating the functions of TC . Moreover, another focus of shipping is average ship size (S). Operation-related variables (Z) might include sailing distance, slot utilization, and freight rate.

Economies of Scale and Density: Evidence From Company-Level Cost Functions

After estimating the company-level cost functions, one can further test the existence of economies of scale and economies of density of the carriers' operation. In general, economies of scale refers to the cost advantage obtained by a firm when UC decreases in output. In a word, economies of scale exists if the average cost of producing one unit of output is above the marginal cost of producing one incremental output. Thus, the ratio of average cost and marginal cost, denoted as EOS, can be used to quantify economies of scale. If this ratio is above 1, economies of scale exists; if it is below 1, diseconomies of scale exists. Based on the definition of elasticity, this ratio is exactly the inverse of the cost elasticity with respect to output. That is,

$$EOS = \frac{1}{\varepsilon_Q}$$

The above definition has been modified in the context of airline operations. As most airlines operate an extensive network, output is affected by not only the amount of output on each route, but also the number of airports served, that is, network size. Therefore, in air transport, EOS describes the impact on cost by having the same proportional changes in both output and network size, while controlling for operation-related factors, such as load factor and stage length. In this case, as both output and network size change in the same proportion, density is kept constant. On the other hand, if the unit cost declines as the airline increases output in a fixed network by adding more traffic on each route, we say there exists economies of density. Therefore, in air transport, the cost function must include network size (N) as a variable, to capture the cost impact of network expansion. Then, we can test the presence of economies of scale and economies of density by calculating the following EOS and EOD respectively

$$EOS = \frac{1}{\varepsilon_Q + \varepsilon_N}, \quad EOD = \frac{1}{\varepsilon_Q}$$

where ε_N is the elasticity of cost with respect to number of airports served. When EOS (EOD) is larger than 1, economies of scale (density) exists. Intuitively, airlines are likely to enjoy economies of density, because if it is possible to generate more traffic on a particular route, larger aircraft can be used and facilities at endpoint airports can be shared by more freight and/or flights. In studies of passenger airlines, economies of density has been widely observed, but economies of scale seems to vanish once the airline reaches a certain size.

In air freight operation, **Table 8** suggests that most of the studies also find stronger density effect than scale effect. Moreover, the conclusion about the existence of economies of scale for cargo airlines might be affected by the choice of functional forms. As shown in **Table 8**, when log-transformed Cobb-Douglas function is applied, diseconomies of scale is observed. However, when translog function is used, the estimated EOS all becomes larger than 1. Another observation is that integrators (FedEx and UPS) have larger EOS and EOD than non-integrators listed in **Table 8**. This may be caused by the different network structures. Integrators rely on hub-and-spoke network (**Fig. 1**) to channel freight via their hubs. As shown in **Table 2**, this network structure may cause integrators to incur a larger share of overhead costs, which is relatively fixed. However, it allows consolidating freight from many different origin-destination markets into one flight and therefore achieving higher density on each route. Most of the non-integrator cargo airlines do not operate extensive hub-and-spoke networks. Instead, their flights are routed in a circular way to visit a number of airports in sequence (**Fig. 1**). This circular routing substantially reduces the number of markets, which can be served by one single flight and makes network expansion more costly.

In maritime shipping, network size is rarely included in the studies. Thus, the definitions of economies of scale and economies of density are not as clear as in air transport. In fact, economies of density is never mentioned in the shipping literature. Instead, EOS is calculated by $1/\varepsilon_Q$ without controlling for network size. **Table 9** suggests that despite being above 1, EOS seems much weaker in shipping industry than in air freight transport. Bulk shipping and tanker seem to enjoy more economies of scale than container shipping. The negative elasticity of ship size (−0.24) means that with fixed output, total cost reduces as ship size increases. This is consistent to the scale economy in terms of ship size. However, its impact seems unclear if fleet capacity is controlled. In other words, empirically, it is unclear what causes the scale economy in shipping. Is it caused by larger ships, larger fleet capacity or capital stock or a combination of several factors? Moreover, it is controversial whether there is a ceiling of economies of ship size. First, the water depth and width of the canals and port channels limits the number of routes that large ships can operate. Large ships may have to take detours and travel longer distances than small ones. Second, the more cargoes a ship carries, the more time it spends for loading

and unloading at port (Cullinane and Khanna, 2000). Third, cost may increase at terminal or inland transport with large ships. For example, cranes at terminals need to be upgraded with longer outreach and connection to inland transportation has to be improved to handle high traffic brought by one single ship (Mason, 2015). The above discussion is based on very limited number of studies, since this issue has not been widely studied in shipping with comparable methods and datasets.

Conclusion

In general line-haul activities account for a much larger share of total operating costs for air freight than sea shipping. Cargo handling at terminals, management of sea containers and inland transportation also account for a lion's share of total cost of moving sea cargo. Despite this cost structure difference, in both transportation modes, there exist economies of vehicle size and, in general, unit costs reduce in load factor and travel distance. Each mode also has its special features. Speed places a significant role in ships' fuel costs, but it has limited impact on air transport. As air freight can be carried either in the freighter aircraft or in the belly hold of passenger airplanes, it further complicates the comparison of air freight cost efficiency. Network structure can affect the cost of container shipping, but to our knowledge this kind of studies are rare in the context of air freight. In fact, combination airlines, which own both passenger airplanes and freighters, might operate both circular and hub-and-spoke networks for cargo, making a direct cost comparison more difficult.

At company-level, both transportation modes apply Cobb-Douglas function or the more flexible translog form to approximate the total operating costs as a function of input prices, output and various other factors. In air transport, the estimated functions are used to measure the existence and degree of economies of scale and density after controlling for network size. However, in sea shipping, network size is never included as a variable and there is no separately defined concept of economies of density. Instead, the choice of variables seems to be inconsistent across studies and so do the results. Overall, empirically it is unclear whether it is the ship size or the company size that leads to lower unit cost in sea shipping.

Introduction

The two basic modes of land freight transport other than pipelines are road and rail, each of which has its own cost structures and external effects. In cost analyses of either mode, the relevant cost concept will depend in any given case on what it is desired to analyze. For measuring expansion of the supply of transport services, incremental cost is to be used, while for analyzing service reduction the applicable notion is avoidable cost. In short-term decisions, fixed cost plays no role; the focus is rather on variable cost. In practice, however, this latter factor is ambiguous given that what is variable in one sense may not be in another. The difficulties involved in identifying the variable costs of a particular freight movement have to do with the multiproduct nature of transport firms and indivisibilities in the production of their services.

The remainder of this paper is organized into five sections. Section “Transport Production and Cost Structure” presents a microeconomic analysis of freight transport production and cost structure, distinguishing between single-origin/single-destination systems with three different points and single-origin/multiple-destination systems. Sections “Road Freight Transport” and “Rail Freight Transport” describe certain specific aspects of road and rail transport. Finally, Section “External Costs” discusses cost externalities characteristic of the two modes.

Transport Production and Cost Structure

Analyses of production processes are based on concepts of inputs, outputs, and technological viability. This section addresses the application of these concepts to the case of transport in which a firm produces load flows between different origins and destinations over multiple time periods. Also addressed in this section are the economies of scale, scope, and density.

The production of freight transport involves the assignment of resources to the generation of trips between different points in space over multiple periods. Measuring a transport process requires a description of the load to be carried, a physical unit of reference, the load quantity (flow), and the origin and destination in space–time (Jara-Díaz, 2007). This last characteristic is what distinguishes a transport product from the traditional product concept. A transport firm uses vehicles, loading/unloading terminals, rights-of-way, energy, labor, and other resources to produce movements of goods from multiple origins to multiple destinations in different periods. The firm’s output is thus a flow quantity between an origin and a destination at a given instant in time, which can be expressed in formal terms by a vector as follows:

$$Y = \{y_{ij}^{kt}\} \in R^{K \times N \times T} \quad [1]$$

where each y_{ij}^{kt} component represents a product flow of type k moved from an origin i to a destination j in period t . Expression [1] is quite general and covers the possibility of handling various types of flow. It should be noted that transport firms produce multiple outputs not just because they may deal in various flow types but also, and primarily, because of the time and space dimensions (i.e., periods and origin–destination pairs). Unlike classical microeconomic theory, these companies are active simultaneously in various markets each having its own demand curve and marginal costs, although the latter tend to be interrelated. The space dimension, much more than time, is the key element that differentiates the transport industry from other economic activities.

Figure 1 Relationship between transportation cost per shipment and shipment size. Source: Daganzo (2005).

For any given level of production, a transport firm must make decisions regarding the quantity and characteristics of the inputs such as the number of vehicles and the number of terminals, the latter including their loading and unloading capacities. The firm must also set the operating rules such as vehicle speeds, frequencies, and load sizes. Since transport takes place over a network the company will also have to plan a service structure, that is, the generic way in which its vehicles will visit the various destinations to produce the desired flows. This set of endogenous decisions defines the route structure, which must be chosen based on spatial information regarding demand, origin and destination locations, and the physical network.

Single Origin–Destination System

In a system consisting of a single origin producing identical products to be consumed at a single destination (Daganzo, 2005), transport costs per shipment can be broken down into a fixed cost (C_f) and a variable cost (C_v). The total mean transport cost in a given period for a sequence v_i of shipments $V = \sum_i v_i$ can be expressed as:

$$CMe = \frac{C}{V} = C_f \left(\frac{1}{V} \right) + C_v \quad [2]$$

Economies of scale arise from the fact that in Eq. [2] all the individual shipments in the sequence share the fixed cost C_f . Cost per shipment also depends on shipment size. Each time this latter factor reaches and exceeds a multiple of vehicle capacity K , an additional vehicle must be dispatched, resulting in a jump in cost per shipment as is illustrated in Fig. 1.

The foregoing implies that the per shipment cost function $f_t(v)$ must be subadditive, that is, it must satisfy the inequality $f_t(x_1 + x_2) \leq f_t(x_1) + f_t(x_2)$ for any $x_1, x_2 \geq 0$. This property is to be expected since it would be counterintuitive for the dispatching of shipments separately to reduce total transport costs.

In the same context of two nodes (1 and 2) we now assume a multi-output firm is operating a backhaul system with two flows (γ_{12}, γ_{21}) and one product in a single period (Jara-Díaz and Basso, 2003), using the same fleet of vehicles to move the two flows. Vehicle frequency (f) in both directions is given in this case by the maximum flow. If we further assume that $\gamma_{12} \geq \gamma_{21}$, the vehicle traveling from 1 to 2 will be fully loaded and the frequency will be given by:

$$f = \frac{\gamma_{12}}{K} \quad [3]$$

If the vehicles are loaded and unloaded sequentially at a rate μ , vehicle speed is v and the distances traveled between the two nodes in either direction are d_{12} and d_{21} , cycle time between 1 and 2 will then be:

$$t_c = \frac{d_{12}}{v} + \frac{2K}{\mu} + \frac{2d_{21}}{\mu} + \frac{d_{21}}{v} \quad [4]$$

Fleet size B is given by f times t_c :

$$BK = \gamma_{12} \left[\frac{d_{12}}{v} + \frac{2K}{\mu} + \frac{d_{21}}{v} \right] + \frac{2K}{\mu} \gamma_{21} \quad [5]$$

Figure 2 Production possibility frontier of a backhaul freight transport system. Source: Jara-Díaz (2007).

The production possibility frontier can be expressed as:

$$y_{21} = \frac{\mu B}{2} - \left[\left(\frac{d_{12} + d_{21}}{v} \right) \frac{\mu}{2K} + 1 \right] y_{12} \quad [6]$$

Eq. [6] gives the set of vectors (y_{12}, y_{21}) representing the output that can be efficiently produced by a fleet of vehicles B each of capacity K circulating at speed v and loading and unloading at a rate of μ . Within this frontier lie all the (y_{12}, y_{21}) combinations that are technically feasible, as shown in Fig. 2.

Total production expenses are obtained from the parameters associated with input prices, which include vehicle fuel consumption per kilometer (g), hours worked by vehicle drivers (ε) and loading/unloading site personnel (θ), wage rates (ω), fuel price (P_g), and price per hour of a capacity K vehicle (P_K) and of a loading/unloading site P_μ . Based on the foregoing, the formula for total production expenses G is given by:

$$G(y_{12}, y_{21}) = C_0 + [P_K + \omega\varepsilon]B + \frac{P_g \cdot g \cdot (d_{12} + d_{21})}{K} \cdot y_{12} + \frac{2 \cdot P_\mu + \omega\theta}{\mu} y_{21} \quad [7]$$

Thus, the optimization problem facing the firm would involve minimizing G with respect to K , μ , and v . Assuming the values of these variables are fixed, that is, the vehicles and loading/unloading sites are only available in a single size and speed is determined exogenously by technical or legal considerations, the cost function can then be formulated as follows:

$$C(y_{12}, y_{21}) = C_0 + y_{12} \cdot (d_{12} + d_{21}) \cdot \Lambda + (y_{12} + y_{21}) \cdot \Omega \quad [8]$$

where

$$\Lambda \equiv \left[\frac{P_K + \omega\varepsilon}{vK} + \frac{P_g g}{K} \right] \quad [9]$$

$$\Omega \equiv \left[\frac{P_K + \omega\varepsilon}{vK} + \frac{P_g g}{K} \right] \quad [10]$$

Note that in Eq. [8] there is a term for flow distance and another for pure flow. This latter term captures expenses incurred while the product is stationary, that is, costs arising from terminal operations, whereas the former term captures route expenses. The presence of these terms draws attention to two aspects of the description of transport firm output. First, if the cost function specification includes only factors relating to distance such as ton-kilometers and average trip length, the real transport production costs may not be properly captured. Second, since flow distance equals frequency times vehicle capacity, it is the term that determines the capacity of the transport system. This means that if the firm's output is a freight flow, for example, the term will be the total number of vehicle-kilometers it "produced." This justifies the use of such aggregates in the literature on transport cost functions. Once a firm has optimized its operations such that flows are produced at minimum cost, route expenses will be directly related to total transport capacity.

Figure 3 Service structures for a three-node network. Source: Jara-Díaz (2007).

Note, however, that the two-node system just outlined cannot give a complete demonstration of the two stages in the optimization process. The second stage, which compares cost functions that are conditional on route structure, is not applicable in this single route structure case. Nevertheless, it will be very useful for explaining the three-node system in which there is a choice of route structures and for comparing costs following an expansion of the network.

Three-Node System

Transport firms are faced with three decisions: the quantity and characteristics of the inputs, the operating rules, and the route structure. Since the third decision is a discrete one, the underlying minimization process may be seen as a sequence of two stages. In the first stage, for each possible route structure in the system the firm optimizes inputs and operating rules. A production possibility frontier is established and, on the basis of input prices, expenses are minimized to obtain a cost function conditional upon the structure that gives the minimum cost for producing a given level of output. Then, in the second stage, these conditional cost functions derived for each route structure are compared and the structure with the lowest cost is chosen.

Now consider an OD structure of six flows in a system of three nodes connected by three links of length d_{ij} . In this basic physical network there is no decision to be made on link sequence so the choice of a service structure and the choice of a route structure are one and the same, a convenient simplification. Maintaining the assumptions of our two-node model in the previous subsection, that is, the same sequential loading/unloading procedure and known values of K , μ , and ν , the objective is to find cost functions that are conditional upon the new route structure.

Three possible service structures for a three-node system with six OD pairs are illustrated in Fig. 3. Structure (A) is a simple circuit, structure (B) consists of three simple cyclical systems, and structure (C) is a hub-and-spoke structure that creates a distribution node (H in the figure), a common configuration in air transport. As regards the assignment of vehicles to fleets, in (A) only one fleet (one frequency) is possible, in (B) there are three fleets, and in (C) there can be one, two (with three alternatives), or three fleets.

In a general counterclockwise cyclical structure (Fig. 3A), which implies the use of a single fleet, the vehicle load size on each of the three segments k_{12} , k_{23} , and k_{31} in the network is defined as:

$$k_{12} = \frac{\gamma_{12} + \gamma_{13} + \gamma_{32}}{f} \quad [11]$$

$$k_{23} = \frac{\gamma_{23} + \gamma_{21} + \gamma_{13}}{f} \quad [12]$$

$$k_{31} = \frac{\gamma_{31} + \gamma_{32} + \gamma_{21}}{f} \quad [13]$$

If we assume arbitrarily that the segment with the highest load is 1–2, then the efficiency condition implies that the vehicle on this segment must carry a full load. Its frequency will thus be given by:

$$f = \frac{\gamma_{12} + \gamma_{13} + \gamma_{32}}{K} \quad [14]$$

Therefore, cycle time is expressed as:

$$t_c = \frac{d_{12} + d_{23} + d_{31}}{\nu} + \frac{2K}{\mu} + \frac{2K(\gamma_{21} + \gamma_{23} + \gamma_{31})}{\mu(\gamma_{12} + \gamma_{13} + \gamma_{32})} \quad [15]$$

The production possibility frontier for this route structure is obtained from the following formula:

$$BK = (\gamma_{12} + \gamma_{13} + \gamma_{32}) \left[\frac{d_{12} + d_{23} + d_{31}}{\nu} + \frac{2K}{\mu} \right] + \frac{2K}{\mu} (\gamma_{21} + \gamma_{23} + \gamma_{31}) \quad [16]$$

This in turn means that the conditional cost function of a cyclic route structure is:

$$C_{CG}(Y) = C_0 + (\gamma_{12} + \gamma_{13} + \gamma_{32}) \cdot (d_{12} + d_{23} + d_{31}) \cdot \Lambda + (\gamma_{12} + \gamma_{13} + \gamma_{32} + \gamma_{21} + \gamma_{31} + \gamma_{23}) \cdot \Omega \quad [17]$$

Figure 4 Hub-and-spoke route structure. Source: Jara-Díaz (2007).

This function is similar to the one obtained for the two-node system. The flow distance term obtained for the present system has the same meaning, that is, the system's capacity, given that the flows involved define the frequency. The pure flow term is generated by the loading/unloading activities. Note also that this function reduces to the two-node version if the four new flows are set to zero and $d_{23} - d_{31}$ is defined as d_{21} .

In a hub-and-spoke route structure, the hub is a node that collects and distributes all flows and is usually either the origin or the destination. Assume arbitrarily that the hub is node 2 and a fleet of vehicles operates at a single frequency. Other structures of this type could, of course, be considered, such as a two-fleet operation, one in 1–2 and the other in 2–3. Here, however, we have opted to develop the one-fleet operation since the others can be constructed using the two-node system, as shown later. Thus, a vehicle loads flows γ_{12} and γ_{13} at node 1, unloads γ_{12} and loads γ_{23} at node 2, then unloads γ_{13} and γ_{23} and loads γ_{32} and γ_{31} at node 3, returns to node 2 to unload γ_{32} and load γ_{21} , and finally goes back to node 1 to unload and start the cycle over again (Fig. 4).

Following the same procedure used in the previous case, we obtain:

$$C_{HS}(Y) = C_o + (\gamma_{12} + \gamma_{13}) \cdot (d_{12} + d_{23} + d_{32} + d_{21}) \cdot \Lambda + (\gamma_{12} + \gamma_{13} + \gamma_{32} + \gamma_{21} + \gamma_{31} + \gamma_{23}) \cdot \Omega \quad [18]$$

In this equation there again appear a flow distance term that represents system capacity and a pure flow term generated by the loading/unloading activities. We have already obtained two conditional cost functions for the three-node system, but by simple analogy we can find conditional functions for another three route structures: a clockwise cyclic system, and hub-and-spoke systems with the concentrator at nodes 1 or 3. The two-node system cost function can also be used to derive conditional cost functions for other cases: direct service with three fleets, each one serving a pair of nodes cyclically (1–2, 2–3, and 1–3) and hub-and-spoke with two fleets, each one connected by a pair of nodes with the concentrator at either of the three nodes. In this latter case, some flows will have to be loaded and unloaded twice (origin, destination, and concentrator). This increases expenses above the levels of the other cases but reduces cycle times. Finally, these examples illustrate how choosing a route structure is a key endogenous element and also show that minimum cost is associated with this choice.

Distribution From a Single Origin to Multiple Destinations

In this subsection, we address the problem of the physical distribution of goods produced at a single origin (the “depot”) to N customers spread over a region of area S with no transshipments. Assume that the N points to be visited are located uniformly and randomly over the indicated area. The expected trip distance is then:

$$L(N, S) \approx k\sqrt{NS} \quad [19]$$

The mean distance per customer is therefore:

$$\frac{k}{\sqrt{N/S}} = \frac{k}{\sqrt{\delta}} \quad [20]$$

where δ is the customer density (customers/m²) in the system. This approximation is better for large values of N . The k term is a nondimensional constant that depends on the metric used to measure distance traveled over the network. If the metric is Euclidean, $k = 0.57$ and if it is Manhattan, $k = 0.82$.

If we consider a region x_o with C stops, the total distance traveled to visit C points within the region (the tour distance) is:

$$\text{Tour distance} \approx 2\bar{r} + \left[k\delta^{-1/2}(x_o) \right] (C - 1) \quad [21]$$

where $\bar{r}$ is the average distance from the C points in region x_o to the depot along the shortest route.

The first term in Eq. [21] may be interpreted as the mean distance from the depot to the center of gravity of the points in the region, while the second term is the local distance a vehicle must travel to deliver and pick up a load. Thus, if there are N/C tours, the total distance traveled is approximated by:

$$\text{Total distance} \approx \left\{ \frac{2E[r]}{C} + kE(\delta^{-1/2}) \right\} N \quad [22]$$

If the density is uniform, that is, $E(\delta^{-1/2}) = \delta^{-1/2} = \sqrt{S/N}$, then:

$$\text{Total distance traveled} \approx \frac{2E[r]}{C}N + k\sqrt{SN} \quad [23]$$

Regardless of the points' specific locations, if cost must be estimated before they are known, Eqs. [22] and [23] will be very useful. Comparisons made by Hall et al. (1994) indicate that these two approximation formulae are quite accurate even if the number of stops is not the same for every tour.

Economies of Scale

The concept of economies of scale refers to the amount of increase in output brought about by an equiproportional increase in the amounts of all inputs. The degree of multiproduct economies of scale S can be defined as the maximum expansion of output Y , denoted $\lambda^S Y$, obtainable by expanding the input vector X to λX . In analytic terms,

$$F(\lambda X, \lambda^S Y) = 0 \quad [24]$$

where F is the production function relating outputs to inputs. The value of S may be greater than, equal to, or less than 1, indicating that returns to scale are, respectively, increasing, constant, or decreasing. It is calculated as follows:

$$S = \frac{C(Y)}{\sum_i Y_i \frac{\partial C}{\partial Y_i}} = \frac{1}{\sum_i \eta_i} \quad [25]$$

and

$$\eta_i = \frac{Y_i}{C(w, Y)} \frac{\partial C(w, Y)}{\partial Y_i} \quad [26]$$

where η_i is the cost elasticity of output i , C is the cost of production, and w is the input price vector.

Economies of Scope

The concept of economies of scope is used to analyze the economics of joint production of multiple products. The degree of economies of scope SC_R for a subset R is defined as:

$$SC_R = \frac{1}{C(Y)} [C(Y_R + C(Y_{M-R})) - C(Y)] \quad [27]$$

where Y_R represents the vector Y , M is the set of all products, and $y_i = 0, \forall i \notin R \subset M$. Then, if SC_R is positive, it is cheaper for Y to be produced by a single firm than by two different firms where one produces subset R and the other subset $M-R$.

In the sections that follow we analyze the cost structures for road and rail freight transport, including the external costs attendant upon each mode.

Road Freight Transport

Road transport is today the dominant mode for moving a wide variety of load types. The key advantage of truck haulage is that it allows loads to be picked up and delivered at locations not accessible by other modes (Webster, 2009). This section discusses road transport cost structure and vehicle capacity utilization.

Broadly speaking, the trucking industry is segmented into truckload (TL) carriers and less-than-truckload (LTL) carriers. TL shipments generally move from a single origin to a single destination on fully loaded vehicles, whereas LTL shipments occupy a certain percentage of a truck's capacity, allowing operators to consolidate multiple shipments in a single vehicle. Compared with TL, LTL shipments are more costly per ton and have longer shipping times, and the goods carried are more exposed to damage given that they are routed through various consolidation centers where loads are interchanged. In the United States, TL shipments make up 52% of the total and LTL shipments about 24% (Hooper and Murray, 2017).

A truck can cover approximately 800 km/day, of which empty returns account for about 20% in the United States and 20%–35% in the EU. Operating costs are subject to a series of underlying impacts and externalities. As a result, some expenses like fuel and tires can be measured relatively easily, but calculating labor costs may be complicated by the effects of driver experience, productivity, and differences in compensation models.

The marginal costs of road transport can be divided into two general categories. The first category is related to the trucks themselves and includes expenses such as fuel, lease or purchase payments, repairs and maintenance, vehicle insurance, and permits and special licenses. The second category covers driver expenses such as wages and fringe benefits.

Data from the US-based American Transportation Research Institute (ATRI) show that the marginal cost per mile in the United States is about US\$1.60 (Table 1) while marginal cost per hour, at an average speed of about 40 Mph, is on the order of US\$65 (Table 2).

A key factor impacting directly on operating costs is vehicle capacity utilization given that it is an indicator of how economic resources are being employed from the standpoint of both the operator and the customer (Ben-Akiva et al., 2013). Despite its positive contributions, road transport produces negative externalities that must be mitigated, though ideally not at the cost of economic prosperity. Improving vehicle capacity utilization would make it possible to lower the vehicle mileage required to satisfy freight transport demand and thereby also reduce the related external effects. This points up the importance of strengthening our understanding of the factors behind vehicle capacity utilization and how it influences global demand for freight transport trips.

Unlike the case of passengers, freight rarely returns to its point of origin, so freight vehicle use on return trips is less efficient. This is known as the backhaul problem. Raising the efficiency of available vehicle capacity on trips in the two directions thus depends on the extent to which the trucks travel loaded. The cost complementarities between the two legs of a round trip impel transport firms to serve multiple markets in order to minimize costs. EU statistics show that between 15% and 38% of total truck travel consisted of empty returns; estimates for developing countries range between 30% and 35%.

Studies of this topic may be divided into two groups according to their analytical approach and field of origin. The first group looks at utilization from the standpoint of economic theory, which assumes the objective of a firm is to maximize profit and examines how utilization is influenced by various characteristics of the firm and the transport market. The second group, meanwhile, proceeds from the viewpoint of the transport literature and analyzes vehicle movement and utilization in the context of transport demand models.

In studies based on economic theory, vehicle capacity is underutilized as a result of the constant challenge to equate capacity with demand due to the imbalances in the movement of goods between regions and differences between truck operators in market access costs. Freight imbalance is an external (exogenous) problem that operators can minimize, at least in the long run, only by choosing an appropriate location for their base of operations close to the main generators of traffic. In practice, however, operators have to make continuous market access decisions as part of the process of adapting specific demand levels to specific levels of capacity based on net income considerations. As a result, to the extent there exist differences in access costs not related to distance, in any given market segment there will be some vehicles carrying loads while others run empty. Recent studies in this literature highlight the

abilities of information technologies to equate capacity with demand, allowing operators to reduce market access costs and thus maintain their vehicles loaded and on the road at higher frequencies.

The transport literature, on the other hand, focuses on the relationship between the “trip chain” and the vehicle routing problem faced by operators in the context of urban freight transport, where utilization levels are lower than those experienced in long-distance operations. The trip chain approach to freight movement analysis can significantly improve modeling of demand for freight transport.

Rail Freight Transport

Rail transport is a relatively low-cost mode that is attractive for long-distance shipping and heavy loads in situations where dead time and reliability are relatively unimportant. Goods typically shipped by rail include coal, minerals, grains, and wood, as well as motor vehicles and heavy machinery (Webster, 2009).

Variable costs in rail transport are generally lower than those in truck transport, but fixed costs, consisting notably of rolling stock and stations, are higher. Railroads must also shoulder the expense of rail network maintenance. This contrasts with the case of road networks, which are often financed and maintained by governments or through tolls that trucking firms incur as a variable cost.

As with road haulage, rail transport typically offers multiple services involving multiple costs, complicating the task of identifying the cost of moving specific loads (Button and Pitfield, 1985). An example of this is the joint cost of fronthaul and backhaul. Although the supply of transport takes the form of round trips, demand for transport is one way. Many of the variable costs involved are incurred jointly, that is, in both directions, meaning the individual fronthaul and backhaul costs are inseparable. It is conceptually impossible to identify the total cost of a movement separate from the costs of other traffic. It is true that certain rail transport cost items can be uniquely attributable to specific traffic, but most of them cannot. In principle, the cost interdependence of different products requires that the optimal price be set simultaneously for all of them.

Another relevant characteristic of railroads is that their fixed capital is intensive and varied, and increments to it are necessarily discrete and indivisible. An example of such an increment is the construction of a second track to handle high-density traffic operations. The implication is that the cost to the railroad of an increase in traffic is low if there is excess network capacity, but very high if there is not. Thus, for small product increments costs are relatively invariable but for large ones they can vary greatly.

Estimating the private cost of rail freight service is inherently more complex than for similar service in road transport. Among the complicating factors are joint production between railroad companies (e.g., the interchange of track and rolling stock between operators), scale and density economies, and the lack of data on specific expenditures relating to individual movements (Forkenbrock, 2001). Since rail freight operations are highly varied, a single added value for the private cost per ton-mile would have little meaning. Thus, in what follows we present the costs for four different railroad freight scenarios.

1. Heavy unit train: It consists of 100 light (26-ton) cars, each one carrying a load of 105 tons. The trip is 1000 miles long and returns 100% empty. The train is powered by four 3000-BHK locomotives.
2. Mixed freight train: The mixed load is transported in 90 cars each weighing an average of 32 tons. The average carload is 70 tons and trip length is 500 miles, with an empty return rate of 45%. The train is powered by three 3000-BHK locomotives.
3. Intermodal train: It is made up of 120 spine cars carrying an equal number of truck semitrailers. A spine car weighs 14 tons while the average weight of a loaded semitrailer is 28 tons. Trip length is 1750 miles, with an empty return rate assumed to be 5%. The train is powered by three 3000-BHK locomotives.
4. Double-stack train: It consists of 24 light flatcars weighing an average of 80 tons each and carrying 240 containers. The empty return rate is 10%. The train is powered by four 3000-BHK locomotives.

Operating costs are estimated for the four scenarios using average operating parameters and are set out in Table 3. Both the heavy unit and mixed freight scenarios have a cost per ton-mile of approximately 1.2 cents. For the intermodal scenario, the corresponding cost figure is 2.68 cents while for the double-stack scenario it is 1.06 cents.

External Costs

In environmental impact studies of freight transport systems, it is considered a best practice to assign the impact of the system to the production of the load carried. This ensures that the consequences of the entire chain of production, including, for example, the

Table 3 Private operating costs of four railroad freight scenarios

Rail road scenario	Power	Cargo (tons)	Distance (miles)	Average cost per ton-mile (1994 cents)
Heavy unit train	Four 3000-BHP locomotives	10.500	1000	1.19
Mixed freight train	Three 3000-BHP locomotives	6.300	500	1.20
Intermodal train	Three 3000-BHP locomotives	3.360	1750	2.68
Double-stack train	Four 3000-BHP locomotives	6.720	1750	1.06

emissions resulting from the production of the load, are taken into account along with the transport itself. The work done in transporting the load must therefore be calculated as the load mass multiplied by the transport distance (in TKM units). This allows different transport modes to be compared. Another common practice is to look at the impact in terms of 20-foot equivalent units (TEU) and the distance they are transported (TEU-km). These are sometimes given separately for loaded and empty containers (Monios, 2017).

Currently, the emissions that contribute most to global warming are greenhouse gases, the most important of which are carbon dioxide (CO₂), methane, and nitrous oxide (NO_x). CO₂ emissions are produced by burning fuels containing carbon such as gasoline, diesel fuels, natural gas, and biofuels.

Road Transport Externalities

Fuel consumption and emissions in road transport depend on vehicle speed and road topography. In urban zones or wherever traffic is congested, fuel consumption per kilometer may be significantly greater due to frequent vehicle stopping and accelerating. Another major influence on consumption is load mass. Some examples of fuel consumption are summarized in Table 4.

The main parameter determining road transport emissions is the load factor, which may vary significantly for both intermodal and unimodal systems. A high level of empty container repositioning would, of course, have a generally negative impact on environmental performance. Some examples of truck emission standards in the EU are summarized in Table 5.

Rail Transport Externalities

Since 2006, the EU has applied regulations governing diesel locomotive engine emissions of CO, HC, NO_x and PM (Table 6). However, permitted levels (measured in g/kWh) are significantly higher than those applicable to modern road vehicles. In Europe, locomotives generally run on diesel fuel of the same quality road vehicles use.

Table 6 EU emission regulations for diesel locomotive engines

Category	Stage	Net power (kW)	Date	Co (g/kWh)	HC (g/kWh)	HC + NO _x (g/kWh)	NO _x (g/kWh)	PM (g/kWh)
Rail car	IIIA	130 < P	2006	3.5		4.0		0.200
Locomotive	IIIA	130 < P < 560	2007	3.5		4.0		0.200
Locomotive	IIIA	P > 560	2009	3.5	0.50 ^a		6.0	
Rail car	IIIB	130 < P	2012	3.5	0.19		2.0	0.200
Locomotive	IIIB	130 < P	2012	3.5		4.0		0.025
Rail car	V	0 < P	2021 ^b	3.5	0.19		2.0	0.015
Locomotive	V	0 < P	2021 ^b	3.5		4.0		0.025

^aHC = 0.4 (g/kWh) and NO_x = 7.4 (g/kWh) for engines of P > 2000 kW and kW and D > 5 L/cylinder.

Table 7 Life-cycle emissions of CO_{2e} for different electricity generation technologies

<i>Electricity generation technology</i>	<i>CO₂ life-cycle emissions (g/kWh)</i>
Hydropower	4
Wind energy	12
Nuclear energy	16
Natural gas	469
Oil	840

Source: *Monios (2017)*.

Although electric motors do not produce emissions, it is common practice to consider the emissions resulting from the generation of electricity. The amounts produced can vary greatly depending on how the electricity is generated. Although the emission levels from hydro and wind power are very low, those from carbon-based sources are very high (in the case of CO₂, higher even than emissions from diesel engines). Some emissions data for different electricity generation technologies are given in **Table 7**.

Introduction

When traveling to and within geographic areas, individuals use different travel modes like walking, cycling, or variants such as small-wheeled travel modes (skates, skateboards, or push scooters), public transit (bus, metro, train, or rail) or, alternatively, they may choose traveling by privately owned vehicles. However, less sustainable modal choices can generate unintended consequences ranging from traffic congestion, air pollution, climate change, noise, accidents, habitat damage, to name a few. These unintended external consequences, known as *externalities*, give rise to various costs such as time costs of delays due to traffic congestion, health costs, and ecosystem damages caused by air pollution, productivity losses due to fatalities and injuries in traffic accidents, among others (Calthrop and Proost, 1998; EC, 2019; Maibach et al., 2008; Van Essen et al., 2008; Verhoef, 1994). These *external costs* affect society at large because they fall on individuals who are not part of the decision resulting in those costs, but are not directly borne by the individual who has caused them. While the latter might be individuals who have themselves made similar decisions, unless they do so as part of a group, each transport user disregards such external effects when making travel mode choices. These external costs then create a wedge between the private costs faced by the decision maker, and the social costs incurred by society. Without policy intervention, transport users face wrong incentives, leading to inefficient outcomes and to welfare losses. Transport externalities are therefore an example of a *market failure* because in their presence, the market does not allocate resources on its own efficiently in a way that balances social costs and social benefits.

Economic theory shows that net social welfare is maximized when the marginal benefit of an activity (reflected by the price of the activity) is equal to its marginal social cost. Actual policies to achieve marginal cost pricing of transportation require measurement of the social costs related to consumption of transport (EC, 2019). While there are numerous issues related to the quantification of transportation costs, the goal of this chapter is mainly to overview key concepts related to external costs. We provide a definition of external costs, asymmetrical and reciprocal externalities, and market failure, and explain the differences between total, average, and marginal external costs. External costs provide a rationale for government intervention and pricing externalities. By internalizing these costs, externalities are made part of the decision-making process of transport users. This can be done through command and control measures or by providing the right incentives to transport users, namely with market-based instruments. Applying these instruments in an efficient way requires nevertheless detailed and reliable estimates of external costs. Because first-best scenarios are seldom met in the real world, the chapter also discusses why Pigouvian rules set to marginal external costs may not be optimal in second-best settings. For completeness, we further cover the roles of marginal, average, and total external costs (TESc) in policy analysis. The discussion of the key concepts will be illustrated with a highly stylized textbook case. It will also focus on the external costs of the use of infrastructure as a basis for market-based instruments to set transport prices right. Variable and fixed infrastructure costs and related charges are not addressed in this chapter.

External Costs: Understanding the Concept and its Use

Total social costs (TSCs) are defined as the full cost of travel within a geographical boundary. They include all costs due to the provision and use of transport infrastructure plus the external costs (congestion, accidents, and environmental costs). On the other hand, *total private costs* (TPCs) are costs directly borne by the transport user and include wear and tear and energy costs of vehicle use, own time

*The author is thankful to Maria Börjesson for her valuable comments on an earlier version of this present chapter.

Table 1 Policy goals and pricing rules

<i>Policy goal</i>	<i>Pricing rule</i>

costs, and transport charges. The difference between the TSC and TPC costs represents the TEC. TECs refer then to the costs that are not borne by those who produce them, that is, to all external costs within a geographic area caused by a specific mode of transport. Thus, in order to measure them, one needs to know by whom these costs are borne in addition to the amount.

In general, social, private, or external costs can be measured in either marginal or average bases, by cost category (e.g., accidents, air pollution, climate change, noise) and by travel mode (road, buses or motorcycles, rail, and aviation) for passenger and freight transports. The *marginal cost* is defined as the incremental increase in total cost associated with an additional unit of an activity (e.g., number of drivers, road users, vehicle kilometer, road kilometer). The *average cost* is calculated by dividing total cost by total activity.

For certain externalities (air pollution, climate change), average and marginal costs are (approximately) equal to the size of the externality and do not depend on the density of the traffic flow. An extra car on a crammed traffic flow emits the same level of air pollutants as an extra car on a thin traffic flow, *ceteris paribus*. But for other externalities (accidents, noise, or congestion), the costs depend on the density of the traffic flow. An extra car on a road with free flow traffic will cause marginal external congestion costs lower than the average external congestion costs. When an extra car enters the traffic flow, at the moment, the capacity of the road is almost met; it causes marginal external congestion costs to be higher than the average costs.

The need to distinguish between private and social costs and to calculate marginal, total, and average external costs depends on the purpose of the policy analysis and on the policy instrument to be implemented (EC, 2019; Maibach et al. 2008; Van Essen et al., 2008; Verhoef, 1994). Policymakers can have different policy goals and therefore policy instruments must be set in a way to make it possible to reach specific policy objectives. Table 1 presents some examples of policy goals and its associated pricing rules. A more in-depth discussion on the merits of the alternative pricing rules to achieve a specific policy goal or even to help internalize the major transport externalities (accidents, CO₂, air pollution, and congestion) is beyond the scope of this chapter.

The concept of average external cost is typically used in policy analysis concerned with equity among different user groups (e.g., drivers vs. transit riders) or with cost recovery. The *unpaid bill to society* approach typically compares the average external costs of road transport not borne by road users (so excluding congestion costs) with the taxes paid by them to the rest of society net of the expenditures on new road infrastructure. From an equity perspective, the two should balance. But such a balance will not necessarily result in an efficient allocation of resources from an economic point of view.

When the goal is the efficiency usage of the transport system, the concept of *marginal external cost* is typically applied. Users of transport infrastructures can impose different external costs upon society. For example, users can deteriorate the road they use or they can slow down the speed at which other users travel. As such, users should pay for their marginal external costs, and only for these costs. This may be achieved by *marginal social cost pricing*. This will ensure the optimal usage of the infrastructure but not necessary a self-financed infrastructure. The reason is because when *marginal social cost pricing* is used, prices are equal to the sum of the marginal resource cost (e.g., extra cost of driver time, fuel, wear and tear of vehicle, all before taxes) and the marginal external cost (including congestion, air pollution, noise, accidents, and maintenance cost of the infrastructure), for a given infrastructure. Yet, there is no reason to expect the revenues produced by *marginal social cost pricing* to balance expenditures. *Marginal social cost pricing* is therefore likely to lead to surpluses, or, more likely, to deficits (Proost and Van Dender, 2004).

On the other hand, with *average cost pricing* production is self-financing, that is, total costs are equal to total revenues because prices are equal to the sum of financial infrastructure costs divided by its total usage volume. However, if the production of an activity (say for instance trips) is subject to constant marginal and average costs in the long run, then the efficient infrastructure facility (e.g., highway) in the long run will be the one where the collection of tolls (e.g., congestion tolls) just equals the cost of the land and capital embodied in the infrastructure.

Another challenge with *marginal social cost pricing* is that marginal external costs are difficult to estimate due to data limitations. Moreover, in the short run, marginal external costs are linked to constant infrastructure capacity, whereas long run marginal costs do take the construction of additional infrastructure into account. This implies, for example, that short-run marginal congestion costs are, in general, higher than long-run marginal congestion costs. The higher marginal short-run cost is due to the road infrastructure capacity being fixed, and therefore delay costs tend to increase rapidly as another driver enters an already crowded fixed-capacity road. Short-run marginal cost figures are typically more relevant for external cost internalization purposes and therefore for efficient pricing of existing infrastructure. On the other hand, the long-run marginal costs have to consider also the financing of infrastructure extensions.

It should be noted that both marginal and average external costs can be used for social cost benefit analyses. Whether marginal or average cost values are preferred depend on the scope of the analysis. For example, for an analysis of the construction of a new road, the noise costs can best be estimated by average cost figures because there is no existing traffic situation. On the other hand, if an

extension of a road from two to three lanes is being examined, the use of marginal cost figures is preferred because the change in an existing traffic situation is calculated.

Finally, TEC estimates have also a role in policy analysis because they allow to assess the extent of an externality and can provide a basis for comparing the burden of alternative transport modes. For example, the recent 2019 EU Handbook on the external costs of transport presents the TECs of transport for all EU member states by transport mode and cost category for the year 2016. It is shown that the overall external costs for road, rail, inland waterway transport, aviation, and maritime amount to € 987 billion, which corresponds to almost 7% of the total GDP of the 28 EU Member States. It is further revealed that the most important external cost category is accident costs equating to 29% of the TECs, followed by the congestion costs (27%). Climate change and air pollution costs both contribute to 14% of the total costs, noise costs to 7%, and habitat damage to 4% of the total costs. Another finding is that road is the largest contributor, accounting for 3/4 of TECs in absolute terms, and also the mode, which leaves the biggest amount of external cost unpaid.

External Costs: Graphical Analysis

Consider now Fig. 1 where we illustrate a motor-vehicle externality. For simplicity, we consider the case of *peak-period road congestion*. Congestion is usually the largest component of all road external costs in peak periods, whereas off-peak, air pollution, noise, and accidents have been found to be at comparable levels with congestion (EC, 2019). Peak demand generates larger traffic volume, and therefore a larger gap between private and social trip costs. In the horizontal axis, we measure traffic flow defined as the number of cars (Q) and in the vertical axis, we have trip costs.

In what follows, this road constitutes the entire transportation system. All travelers and road vehicles are homogeneous. We further assume that congestion is the only externality, all other markets are functioning perfectly. The road capacity is also fixed. Line D represents the demand for road use. The users' perception of the cost incurred when driving is given by the perceived average cost curve PPC . This curve may differ from the actual average cost curve if, for example, fuel taxes apply. Requiring each driver to pay fuel taxes increases the driver's perceived cost of a trip, raising the average cost curve. For simplicity, we assume for now that no taxes exist in this example.

In a competitive market, car users compare the extra direct benefit they get from one more trip by car, defined as the *marginal private benefit* (MPB) and represented by the demand function D , with the additional explicit private cost they pay to do that extra trip, defined as the *perceived private cost* (PPC). The MPB and the *marginal social benefit* (MSB) are equivalent in our example because external benefits from car usage (e.g., urban agglomeration benefits) are absent. Moreover, D slopes downward, incorporating the assumption that as more trips are undertaken, the value of extra trips declines. The PPC slopes upward as time cost increases with the number of cars on the road.

In addition to the private costs paid by the car users, there are also costs imposed to other users when an individual travels by car. An additional car user faces the average journey time and his presence on the road reduces the speed of all other users and increases their travel times. Consequently, this extra user imposes a negative externality on other users over and above the time costs the additional user faces. Graphically, this means that the *marginal social cost* (MSC) curve lies above the PPC curve by an amount equal to the *marginal external cost* (MEC).

In Fig. 1, we assume that the MSC is equal to the PPC up to a threshold Q_T , denoted as traffic free flow volume. This threshold represents the number of cars at which traffic has reached the assimilative capacity of the road, after which congestion begins to cause time delay damages. After Q_T has been reached, MSC exceeds PPC and grows more quickly. At low traffic flows, users can travel at the

Figure 1 External costs of transportation.

free-flow speed, and the PPC is constant. After the traffic congestion develops at higher flows that cause decreases in speed, the PPC slopes upward.

Without policy intervention and in the presence of such external cost, the competitive market equilibrium, Q_1 , occurs at the intersection of the PPC and the MPB. At Q_1 , society maximizes the market surplus because the benefits to the market derived from the last car user equal the additional cost incurred. The TPC for all car users engaged in driving at Q_1 is given by area $A + B + C$, while the TSC is represented by area $A + B + C + D + E + F$. The difference between these two total cost measures, area $D + E + F$, represents the TEC (of congestion) evaluated at Q_1 . The *total social surplus* at Q_1 is, however, represented by area $G + H + I - D$ and equals the total social benefits net TST.

It is apparent from Fig. 1 that Q_1 is inefficient from a society perspective, as by moving to a quantity lower than Q_1 , say Q_2 , we raise total social surplus to $G + H + I$. In fact, Q_2 is the *social optimum equilibrium* since it maximizes the total social surplus. At Q_2 , the MSB equals MSC for the last car on the road. Because congestion costs are borne by other road users, the road user himself has no incentive to take them into account. This makes commuting on the congested road look artificially inexpensive and, excessive road usage occurs from society's perspective ($Q_2 < Q_1$). To correct this problem some traffic should be diverted to off-peak hours, when roads are less congested, and some car users should switch to an alternative travel mode.

An interesting implication from Fig. 1 is that social optimality does not necessarily imply that the externality should be set to zero. With moderate reductions in traffic flow, the marginal private losses from reducing congestion, as represented by the vertical difference between D and PPC, may outweigh at some point the MEC. Thus, part of a policy challenge is to determine the efficient level of the externality. Yet by leaving the market unregulated, society is worse off than if the activity (driving) had been restricted by regulation. The triangle defined by area D represents the net social cost of unregulated road use or the deadweight welfare loss to society. A *deadweight loss* (DWL) is a cost to society created by market inefficiency. It is an indicator of the degree of market failure caused by a distortion or an externality. The existence of triangle D provides a rationale for government intervention.

External Costs: Additional Remarks

Two remarks are now in order. First, so far congestion has been the only negative externality generated by car usage. As such, only the marginal external costs of congestion were included in the MSC curve in Fig. 1. Yet, multiple externalities coexist in the transport system. Road users also generate air pollution, noise, and accidents. In such a case, the marginal external costs of air pollution, accidents, and noise should too be added up to derive the total MSC curve.

Second, certain transport externalities (e.g., motor carbon monoxide emissions or motor vehicle noise annoyance) create damages not only to the parties producing it (e.g., car users) but also to third parties (pedestrians or nearby residents). These types of externalities are also known as *intersectoral externalities* because its external effect is posed upon society at large. As such, measures of the TEC for these types of externalities that result from multiplying the MEC by the amount of road traffic can be misleading if such costs are mostly borne by exposed individuals outside the transport system.

Take for example the cases of two important externalities generated by car users: congestion and air pollution. While air pollution is an example of an *intersectoral externality*, congestion is an example of what we call an *intrasectoral externality* because it reflects reciprocal inefficiencies in the transport system whereby road users do not account for the external effects of their decisions on other road users. Note, however, that the congestion inefficiency arises from decentralized decision-making of users. Because the producers of the congestion externality and the victims are the same (are within the same transport system), road users are actually paying the sum of external congestion costs, just not in a socially optimal way as seen in Fig. 1. This may then explain why congestion is considered an internal impact for equity analysis (because individuals bear the same amount of delay that they impose). However, for efficiency purposes, congestion should be treated as an external cost because cost bearing and decision making are separated: the sum (over all road users) of the additional delays from an individual road user can be very much greater than the average delay (experienced by each individual), which formed the basis of the decision to travel. Thus, because it is an external cost at the individual level, traffic congestion is economically inefficient. This suggests that individual payments of the car users must be adjusted to reduce the inefficiency of road capacity use due to decentralized decisions. This in turn allows the resource (road) to be put to its highest value use.

But road users also impose *unilateral or asymmetrical externalities* to other parties such as air pollution. With an asymmetrical or nonreciprocal externality, the producer and consumer of the effect can be separated. Note that in the case of air pollution, the perpetrators are still the road users but the victims comprise also the exposed individuals outside the road system. Therefore, it is questionable that road congestion can simply be added to the external costs of accidents and the environment to construct a TEC bill, which road users would have to pay in addition to the infrastructure costs. As explained earlier, in the case of congestion, because the external costs are reciprocal, road users are already paying the sum of external congestion costs. TEC that road users should cover consists of accident and environmental costs generated through their transport activity imposed on individuals outside the transport system.

While understanding who bears the external cost of an activity is important when calculating the TECs associated with a specific activity and externality, the MEC, which is important information to set policies that correct transport prices to account for their societal impacts, is not influenced by whether or not an externality is reciprocal in nature. Note from Fig. 1 that because the $MSC = MPC + MEC$, then a tax equal to the MEC at the efficient traffic level added to the MPC will internalize the congestion externality and result in the efficient traffic volume Q_2 . Finally, transport externalities interact with other markets outside the

transport sector and have feedback effects. As such, their effects should be examined in a context of dynamic efficiency. Next, we discuss how underpriced road congestion can affect modal split and the labor and land markets.

External Costs and Travel Mode Choice

We have seen that when there is a discrepancy between transport prices and social costs this leads to an inefficient demand for transport. Since these discrepancies differ between travel modes, the modal split of transport will also be suboptimal with unpriced congestion. **Fig. 2** illustrates the choice between using car or public transit in the presence of unpriced congestion.

Let total demand be given and set to 1, divided between car demand n and public transit demand $(1 - n)$. In the horizontal axis of **Fig. 2**, we measure the proportion of individuals that commute by car and by public transit. In the vertical axis, we measure trip (generalized) costs for users. In the case of the car, the trip cost includes maintenance costs and fuel consumption, and the time cost is defined by the congestion rate on the road. In the case of public transit, the trip cost is the fare price and the time cost is defined by the time on board and waiting time.

The decision whether to undertake a trip or not is determined by whether an individual considers the *generalized cost* (the sum of the monetary and nonmonetary costs of a trip) to be smaller or greater than the benefit contained in reaching his destination. Should the individual decide that he will undertake the trip, he chooses the travel mode with the lowest generalized cost.

Note that we represent the cost of public transit by a constant average cost per passenger, while the PPC of car use is upward sloping as discussed before. We further assume that crowding externalities in public transit are addressed using increases in frequency so that the average generalized cost of public transit is constant. This implies that the marginal social cost (MSC_p) and the private cost (PPC_p) for public transit are the same but, the marginal social cost of using the car (MSC_c) is higher than its perceived private cost (PPC_c).

In the absence of policy intervention, individuals only make travel mode choices based on their private costs. Therefore, the unregulated market equilibrium occurs when the PPC_c equals MSC_p . At this point, an individual is indifferent between the two travel modes. When the PPC_p is smaller than the PPC_c , the individual chooses traveling by public transit; otherwise, the car is the preferred travel mode because it exhibits the lowest generalized private cost. At this unregulated equilibrium, there are n_1 car users and $(1 - n_1)$ public transit riders. This market allocation across the two modes is nevertheless inefficient because car users do not take into account all the costs of commuting by car. Since the trip benefit is the same for both travel modes, the welfare optimum is obtained by minimizing total user costs for all travelers. This requires that the optimal allocation across the two travel modes be where the MSC_c equals MSC_p . In the social optimum, the number of car users would be lower ($n_2 < n_1$). Policy action that either disincentives car usage or increases the attractiveness of public transit can then reach n_2 .

In a first-best scenario, all travel modes should pay their marginal social cost. This suggests that car users should pay in addition to their private costs a congestion tax equal to the MEC so that the congestion externality is internalized in their travel mode choices. However, when road congestion pricing is either not feasible or politically unacceptable, public transit subsidies often emerge as a useful component of second-best policies designed to alleviate the external costs in the transport sector (De Borger and Swyssen, 1999). The rationale for public transit subsidies is that public transport is a substitute of private road use and therefore lower transit fares encourage a shift from automobile use to public transit modes, thereby reducing the social costs from congestion, air pollution, and accidents. The welfare change from the induced substitution into transit depends nevertheless on the relationship

Figure 2 Modal split in the presence of external costs.

between the transit fare and the marginal social cost of service provision (Small and Verhoef, 2007). If the fare is less (greater) than the MSC_p , the increase in demand for public transit produces a welfare loss (gain).

External Costs and Transport–Land Use Interactions

One other issue associated with congestion is that the average commute distance is too long from society's perspective, and it should be shortened. Excessive long average commute means that cities are too spread out. Therefore, by causing people to commute too far, road congestion can lead indirectly to urban sprawl (Brueckner, 2000, 2007). Fig. 3 illustrates how external costs in transportation can affect land use in a simple monocentric city setup.

Assume a linear city with a single central business center (CBD) located at point zero. All workers live in the city, commute by car to the CBD to work, and face commuting costs. The horizontal axis in Fig. 3 represents distance from residence to the CBD, x . The commuting cost from a residence site from the CBD equals the commuting cost per round-trip mile times x .

Workers consume a numeraire composite good and a fixed amount of housing services (measured by acres of residential land for simplicity) taking into account their budget constraint. Given perfect mobility (zero moving costs) and identical workers, the urban equilibrium must yield the same utility level for all individuals. Spatial variation in residential land rent then allows equal utilities throughout the city. This generates a residential land bid-rent function decreasing with distance from the CBD, $R_1(x)$, as depicted in Fig. 3. Workers living far from the CBD are compensated for their long and costly commutes with a lower land rent relative to close-in locations. In a market for residential land with identical workers and no variation in land features aside from the distance from the CBD, the equilibrium residential land rent equals each worker's willing to pay for residential land at each location.

At each location from the CBD, land is allocated competitively either to residential use or agriculture. Agricultural land rent is spatially invariant and equal to R_a . Then the market city's equilibrium size, x_1 , occurs where the land bid rent curves intersect. To the right of x_1 , it is the agricultural bid rent that is higher, so that only agriculture secures land. To the left of x_1 , the bid rent for agricultural land is less than for housing so that all land up for bid is secured by urban residents. However, in the presence of road congestion, x_1 is not the optimal city size because commuting costs are underpriced.

When commuting costs increase (e.g., because of a road congestion tax), commute trips of any given length become more expensive, and as a result, close-in locations become more attractive given the original pattern of residential rents. The desire of workers to move closer to the CBD bids up central rents and reduces rents at more distant locations, causing a clockwise rotation of the residential bid land rent. This explains the location of the social residential bid land rent function, $R_2(x)$, in Fig. 3 relative to $R_1(x)$. The social optimal city size occurs where $R_2(x)$ intersects R_a yielding a smaller feasible area of residence ($x_2 < x_1$).

Thus, any policy intervention that either increases transportation costs or affects land-use practices can help curb traffic-induced externalities and push the city size to x_2 . In such a context, land-use regulations by changing population distribution emerge as another potential second-best tool when road congestion pricing has either large implementation costs or limited political acceptability. For instance, Brueckner (2007) and Anas and Rhee (2007) have investigated the efficiency of an urban growth boundary relative to a congestion toll and Kono et al. (2012) have evaluated the efficiency of regulations on building size and city size relative to the gains that can be achieved by a first-best road toll. More recently, Tikoudis et al. (2018) and Kono and Kawaguchi (2017) consider road tolls and floor-to-area ratio regulations simultaneously. All these studies have shown that in a monocentric city, residential locations should be centralized by optimal land-use regulations when there is only car commuting as in Fig. 3.

Figure 3 External costs and land use.

Figure 4 Transport external costs and labor market.

However, [Buyukeren and Hiramatsu \(2016\)](#), in assuming a congested car mode and an uncongested public transit mode, show that an expansionary UGB would be optimal under certain conditions.

External Costs and Labor Market Interactions

The primary means to raise revenues to fund the provision of public goods is through income taxes, which are taxes on wages that distort the labor market. The Deadweight Loss (DWL) of a tax occurs if there is no divergence between marginal private and marginal social cost. In such a situation, a tax (such as revenue-raising taxes) reduces the economic surplus that could be gained from an activity. [Parry and Bento \(2001, 2002\)](#) have examined how unpriced congestion and other road transport externalities interact with pre-existing distortions in the labor market. Next, we illustrate a simplified version of their theoretical analyses using both [Figs. 1 and 4](#).

[Fig. 4](#) represents the labor market where an initial income tax t_L applies to labor. Income tax revenues are assumed to be lump sum redistributed and the purpose of transport activity is just for people to get to work. We further assume that people commute to work using a congested road.

For simplicity, let us assume constant returns to scale in production and that labor is the only primary input, $Q(L)$. This in turn implies a perfectly elastic labor demand curve as seen in [Fig. 4](#). The labor demand curve shows the value of the marginal product of labor. With constant returns to scale the marginal product of labor is constant as total quantity changes. This makes the production function homogeneous of degree one, which can be represented as $Q = \frac{\partial Q}{\partial L}L$. Because labor is paid at a rate equal to its marginal product value, $w = p \frac{\partial Q}{\partial L}$, then the complete value of the production will be distributed to the labor factor, since $pQ(L) - wL = pQ(L) - p \frac{\partial Q}{\partial L}L = pQ(L) - pQ(L) = 0$. Hence, firm profits are zero. Moreover, since labor demand is perfectly elastic, the equilibrium amount of employment is determined by labor supply as illustrated in [Fig. 4](#). Note that in [Fig. 4](#), labor is measured by number of workdays (with daily workhours fixed) and not by number of workers. Also, a tax on labor income is a distortion because it reduces the supply of labor, resulting in a less than efficient level of employment. So, now the question is to understand how might this distortion affect the prescriptions for a road congestion tax.

Individuals face a tradeoff between work and leisure. Individuals decide the optimal number of working days by equating the private benefit from an extra day of work (the net-of-tax daily wage) with the private cost. The daily wage before taxes is represented by W_1 but after taxes is represented by $W_1 - t_L$. The private cost is the value of leisure time forgone by working and commuting an extra day plus commuting cost. Thus, if the labor supply curve is upward-sloping over some range of net wages, it means that a higher opportunity cost of leisure induces people to take less leisure and work more. If the net wage is only $W_1 - t_L$, then workers choose L_1 working days. The income tax imposes an excess burden or deadweight loss on the economy equal to the triangle area DWL_1 . The rectangle defined by $t_L \cdot L_1$ in [Fig. 4](#) represents the income tax revenues.

From [Fig. 1](#), when road users ignore the MEC of congestion, traffic flow is Q_1 at price P_1 , resulting in a DWL of area D . In contrast, if congestion was internalized, then the DWL in the transport market would be zero, traffic flow would be smaller ($Q_2 < Q_1$), and trip costs would rise from P_1 to P_2 . This change in trip costs has implications for the labor market. Note that the supply of labor depends on work commuting trip costs. A change in commuting costs shifts the labor supply curve because it affects the overall return to work effort relative to leisure.

If leisure and work are substitutes in consumption, the increase in commuting trip cost causes substitution of leisure for work (and also commuting). As a result, labor supply shifts leftward from $S(P_1)$ to $S(P_2)$, which reduces both the amount of labor supplied from L_1 to L_2 and tax revenues in an amount equal to the shaded rectangle T . Therefore, unpriced congestion generates a welfare loss in the transport market given by triangle D in Fig. 1 and an increase in income tax revenues in the labor market equal to area T in Fig. 4. This increase in income tax revenues partially offsets the external congestion cost in the transport market. The general equilibrium social loss from unpriced congestion thus appears to be less than would be anticipated on the basis of a partial equilibrium analysis where the income tax distortion is ignored. The net welfare effect of introducing a policy that would correct the road congestion externality would equal area $D-T$.

But as explained earlier, unpriced congestion also affects the land market and therefore, the general equilibrium effects of such unpriced road externality and internalization policies can be quite complex. Moreover, a labor supply model, which also allows for optimally chosen daily workhours, implies that (monetary and time) commuting costs increase the number of hours worked per day, and thus the effect on total labor supply is ambiguous. And, if individuals can only choose the optimal number of daily workhours (and thus cannot adjust the number of working days), then the income tax would not help internalizing congestion as seen earlier. Note that in order to go to work, it is necessary to commute. Thus, a labor tax and the road congestion charge (which is set per round-trip or equivalently, per workday) have the same effect because they both affect the same choice margin, whether to work or not. But if road users cannot adjust workdays then the two fees do not affect the same choice margin anymore.

Another factor to take also into account is that workers may react quite differently to an increase in monetary commuting costs than to a decrease in wages. Furthermore, commuting time may even reduce workdays if the number of working days can be adjusted. Therefore, the effect of commuting time and monetary commuting costs on total labor supply is ambiguous, as it is not clear a priori whether the effect on daily hours or workdays dominates.

All of these cases highlight the complexity of the interactions of road congestion pricing with preexisting distortions in the economy. But are also extreme examples because in reality, there is no strict proportionality between labor supply and commuting, labor markets are not perfectly competitive, not all trips are work-related trips and commuters are an heterogeneous group. In general, this means that the results discussed earlier may play a weaker impact in reality (De Borger, 2009; Van Dender, 2003). Finally, it is important to keep in mind that labor taxes exist for more than one reason, being one notable motivation a desire for income redistribution. Later in the chapter, we will discuss further more second-best issues and draw additional conclusions on how second-best analysis can help improve the practical implementation of congestion charging systems. Because the literature on the second-best analysis is vast, this chapter still makes no attempt at providing an overview, referring the interested reader to a concise discussion in Small and Verhoef (2007).

Policies for Obtaining Social Optimality with External Costs

Internalization is a way to ensure that each transport user pays the social costs associated to his individual trip. It can be done by a variety of methods and instruments. So far, our discussion has focused mostly on price instruments and in particular road congestion charges. But fuel taxes and cordon charges are other examples of the so called *market-based instruments* because these policies also use economic incentives through price-based measures to regulate the level of the externality. On the other hand, vehicle standards, fuel standards, driving restrictions, low emission zones, parking restrictions are examples of *command-and-control instruments* because they are imposed on private actions by government through regulation (such as setting standards, targets, or process requirements). A combination of these two basic types of instruments is also possible, e.g., taxes differentiated to Euro emission classes of vehicles. For the purpose of illustration of both general approaches, let us consider again the externality described in Fig. 1.

A *Pigouvian tax* is a tax named after A.C. Pigou (1920) that imposes the external cost on the perpetrator of the externality. Where MEC is represented by vertical difference in MSC and PPC in Fig. 1, a Pigouvian tax is determined by the vertical difference in these two lines at level Q_2 , P_3-P_2 . When the marginal tax equals the MEC of congestion associated with Q_2 , the road user bears the full costs of his travel mode choices, and thus the PPC in the presence of this tax (known as a *congestion tax*) reflects the MSC. In this case, $Q_1 - Q_2$ represents the number of road users who will find other ways (e.g., time or mode) of travel or cancel the trip all together. The net gain from a congestion tax is represented by triangle D in Fig. 1 and results from subtracting the deadweight loss of the tax (triangle F) from the avoided external cost ($F + D$).

Four remarks should now be made. First, the appropriate tax to internalize the externality is the marginal and not the average external cost, the latter being lower. Second, because the external cost of transport consists of several elements (e.g., noise, air pollution, accidents), which are assumed to be additive, it follows that the optimal internalization strategy prices transport activities at their total marginal social costs. Third, the coexistence of multiple externalities within the transport market and their spillover effects to markets outside the transport sector requires that a first-best analysis be conducted with a general equilibrium framework. As seen in Fig. 4, when congestion is internalized, labor force participation is discouraged at the margin because of the reduction in the wage net of taxes and commuting costs. Also, changing the modal split is not an explicit goal of a congestion internalization strategy, but such change can be induced as seen in Fig. 2. Pollution affects the level and composition of economic activity which, in turn, affects the level of pollution. Thus, feedbacks in terms of compensated demand responses affect the size of the realized benefits of an internalization policy. Fourth, because a tax is being used to internalize the externality, the government gains the area $(P_3 - P_2) \times Q_2$ in tax revenues. The tax revenues is not of itself an economic cost but it represents a transfer to the rest of society.

The use of these revenues is an integral part of the internalization policy, but the goal of internalization is not revenue raising but holding users accountable for their external effects. Under the Pigouvian tax framework, the revenues are not supposed to go to those affected by the externality as such would lower their incentive to avoid the externality below efficient level. For the same reason, it should not be used to directly reimburse those responsible for the externality.

Consumer surplus is typically used by economists to measure how well-off individuals are. It is defined as the difference between the total amount that *consumers* are willing and able to pay for a good or service (indicated by the demand curve) and the total amount that they actually pay (the market price). It is interesting to observe from Fig. 1 that drivers lose consumer surplus under the Pigouvian tax, which may explain why it is politically difficult to introduce road charging. The welfare gain of internalizing the externality is small relative to the loss in consumer surplus and the gain in tax revenues. Opposition to road charging can be even stronger when demand is more inelastic (lower responsiveness to price) as tax revenues and loss to drivers both increase and, the DWL from excessive congestion is smaller. It is then in such a context that attention in the congestion pricing literature has moved to more realistic types of second-best congestion pricing, in which various costs or constraints deter or prevent the setting of first-best tolls. Examples of second-best tolling include the use of toll cordons around cities instead of tolling each road in the network or the use of step tolls instead of smoothly time-varying tolls. The literature has also studied how other more politically feasible policies may help mitigate congestion costs in a second-best setting. One of such examples is the use of public transit subsidies.

The use of a command-and-control policy such as driving restrictions can also be represented in Fig. 1. Since Q_2 represents the social optimal number of cars in the road, the government may limit the number of cars that can circulate to Q_2 . With the imposition of such regulation, traffic flow is reduced from Q_1 to Q_2 , which again induces a price increase from P_1 to P_2 .

In an ideal world, Pigouvian taxation and command-and-control regulation would be identical as seen above. In practice, there are complications that may make taxes a more effective way of dealing with externalities. Which approach leads to the most efficient regulatory outcome depends on the heterogeneity of travelers and travel mode being regulated, the flexibility embedded in quantity regulation, and the uncertainty over the costs of externality reduction. For instance, in the case of global warming, the marginal damage is fairly constant over large ranges of emissions and thus emission reductions. If costs are uncertain, then taxation leads to a lower DWL than does regulation. On the other hand, if marginal damage is very steep and costs are still uncertain, the result is reversed.

Internalization in Second-Best Settings

As already discussed, first-best pricing requires that the MSC pricing be set throughout the whole transport network or for all competing modes. If limited to a single travel mode (e.g., car) or only a part of a network (e.g., highways), this may give rise to a shift from the priced travel modes or parts of the transport network to the other network parts (e.g., uncongested roads) or travel modes (e.g., public transit). From a welfare point of view, this could lead to lower positive welfare effects.

In addition, the MEC varies with traffic conditions, speed-flow relationships, vehicle type, capacity demand, the value of travel time, and vehicle's occupancy. Thus, a first-best Pigouvian tax system requires not only knowledge about demand, PPC and MSC so that a tax can be calculated but, it also needs to be able to differentiate price levels according to drivers for the various external costs. This requires a technological system, which may be complex or expensive to use. In the case where prices cannot differ by user group and take into account all these dimensions of heterogeneity, it is shown that the second-best tax is a weighted average of the MECs for different groups (Small and Verhoef, 2007).

The question is then to understand what should be the second-best pricing scheme, which aims to achieve efficiency under second-best scenarios. In practice, actual congestion pricing schemes (e.g., cordon schemes, partial charging like toll roads, or HOT lanes) are expensive and imperfect. Because they do not involve perfect marginal cost pricing, the gains are also smaller than under first best. Moreover, second-best settings come in several variants as already exemplified in this chapter. So, to gain additional insights of the second-best issues for road charging, we now turn the discussion to other different sources of second-best distortions in isolation.

Coexistence of multiple externalities or other types of distortions in the same market: If market power from a monopoly is taken into account, then the tax that maximizes social welfare is not the same as when the monopoly distortion is absent. A tax based only on MEC ignores the social cost of further output contraction by a monopolistic perpetrator whose output is already below an optimal level. Ideally, we could have a policy to increase the production level together with a tax to control the externality. But if the product market distortion cannot be directly corrected, then the tax must achieve an optimal second-best tradeoff of distortions (Small and Verhoef, 2007). Corrective taxes reduce external costs but they add to the DWL attributable to the monopolist's restricted output.

As discussed earlier, the coexistence of multiple externalities implies that the level of one externality (e.g., congestion) code-termines the level of the others (e.g., air pollution, accident, noise). Any policy directed toward one of these external costs will also affect the others (Bento et al., 2006; Mayeres, 2000; Parry and Bento, 2001, 2002). This in turn affects how one should calculate the welfare effects of a policy intervention and measure its effects on TECs. Take again the case of a congestion tax. A congestion tax set to the MEC internalizes the externality on the congested road but it exacerbates congestion, air pollution, and potential accidents on competing roadways. In addition, permanent shifts in the demand for travel between modes lead to changes in transport infrastructure investments. Because there are also distortions between the MSB and the MSC of investment in different travel modes, these changes induced by a policy that alters the level of an externality may give rise to significant welfare effects (net benefits) and excess burden (or gross cost).

Distortions in other markets: Similar problems can emerge if a corrective policy is implemented in a market when distortions exist in other related markets as seen in Fig. 4. The potential for a double dividend may nevertheless emerge because the tax revenues from internalizing an externality can be used to reduce preexisting distortions in a revenue-neutral way (e.g., cut labor taxes) (Parry and Bento, 2001, 2002; Proost, 2011). For instance, Arnott et al. (2005) identify a potential triple dividend from the pricing of parking in downtown areas: reduced search for on-street parking, reduced urban traffic congestion, and use of parking revenues to lower other taxes.

Long-run approaches: Most efforts to estimate the MSC and the MPC of travel have focused on short-run costs. However, transport costs and land use patterns are interlinked as seen in Fig. 3. Changes in transportation costs can induce long-run changes on where people reside and work with implications for the calculations of the MSC (Zhang and Kockelman, 2016). Over time, individuals may change their place or time of work, or move house, in order to save time (Downs and Downs, 2004), although taxes that increase the cost of choosing appropriate vehicles or moving home act against this. In general, static monocentric models show that congestion pricing, both in first and second-best settings, increase population density toward central locations. Fig. 3 provides the intuition for such an outcome. On the other hand, when firms' locations are endogenously determined, congestion pricing seems to disperse jobs, though the existing results are highly dependent on the framework and assumptions. In any case, a policy implication of such result is that to achieve city-wide welfare gains, efficient land-use regulations should allow job decentralization. Studies that have examined second-best congestion pricing in a monocentric city with distortionary, rigid regulatory mechanisms in the housing market (e.g., building height restrictions, zoning and property taxation) show that a Pigouvian toll retains its optimality under any setting with quantity restrictions in the housing market (Tikoudis et al., 2018). However, the extent of the quantity restriction determines the volume of the welfare gains in a nonmonotonic fashion. On the other hand, when congestion and misallocation of jobs within the city coexist, a Pigouvian tax strategy is not a social optimum as this strategy cannot solve two problems simultaneously.

Parking Interactions: Another major source of inefficiency in transport markets, especially in urban settings, is parking underpricing, particularly at the workplace (Franco, 2017, 2019; Shoup, 2005). Most drivers do not pay for the resource cost of their parking spot nor for the external costs of cruising for a parking space. Parking costs are nevertheless part of the generalized cost of using the car. Therefore, reducing parking supply or increasing parking prices would increase the PPC of using the car and thus, reduce car journey, increase the use of alternative travel modes and tackle road use externalities, especially peak-period congestion in high density urban core areas (Shoup, 2005). Existing studies have shown that parking fees and area-based tolls for entry into or traveling within a defined area (e.g., a cordon charge) need to be examined simultaneously (Calthrop et al., 2000; Small and Verhoef, 2007; Verhoef, 2005). In the absence of efficient parking fees, the optimal level of a cordon toll rises. The highest welfare gains are nevertheless obtained when both policies are implemented. However, efficiency gains require that the parking fee be borne by the employee and not the employer (Brueckner and Franco, 2018; Franco, 2019). One striking result from the existing literature is that the sole use of parking fees can generate greater welfare gains than the sole use of just one cordon charge, suggesting that parking policies can be used in place of road pricing. However, both policies are imperfect tolls and thus future research should be done to understand further the welfare and efficiency effects of road pricing in the presence of free and subsidize parking.

Conclusions

In the transport sector congestion, air pollution, noise, and accidents are sources of inter or intrasectoral external costs leading to welfare losses and an inefficient market equilibrium. External effects arise if marginal private user costs deviate from marginal social costs. Marginal social cost pricing means setting generalized prices equal to the sum of marginal producer costs, marginal private user costs, and marginal external costs. By charging the optimal price, external effects are internalized and taken into account by transport users. Under such an approach setting, the right prices provide the right incentives to achieve market efficiency and maximize social welfare.

Such right incentives follow from a solution of a well-established model of social welfare. The solution requires charging a tax equal to the difference between marginal social costs and private average costs of traveling to restore the socially optimal equilibrium. Since first-best conditions may not exist in reality, second-best solutions are required, and workable instruments have to be developed with respect to technology, transaction costs, and social acceptance. Insights from the first-best solution may nevertheless help to develop a second-best pricing strategy.

Another challenge is how to define an optimal bundle of instruments to achieve a desired pattern of the transport system. Since different price instruments are likely to be introduced for different types of external effects to optimize the triggers with respect to effectiveness issues, it may be the case that interdependencies between instruments either affect multiple externalities or be counterproductive to other objectives.

In addition, the introduction of charges to internalize external costs leads to revenues. Yet the aim of internalization is not revenue raising but holding transport users accountable for the externalities they create. Yet, the revenues generated by an internalization policy can be used to attain other goals. For example, applying revenues from congestion charges for providing alternatives, e.g., investment within the modes, helps in gaining public support.

Finally, good assessment and monetization of the TECs of the transport sector is also a prerequisite when it comes to target-based internalization strategies (Musso and Rothengatter, 2013). In such a context, social welfare is understood as a bundle of long-term economic, environmental, and social targets summarized by different indicators which the market fails to achieve. External

costs associated to existential risks for human life, nature, climate, or cultural heritage can help establish safe minimum requirements for target achievement. This type of external costs, however, cannot be traded-off against monetary compensation nor be integrated into a social cost function in additive way as seen in the traditional marginal social cost approach. Moreover, it is important to define the share of the different sectors (transport, energy, industry, households) in the overall target achievement (e.g., a GHG reduction target by a certain date). This requires knowledge of the TECs generated by each sector to understand their burden (e.g., transport) and the burden of their subsectors (e.g., road transport). Internalization in this context then requires an adjustment of the market mechanism in the transport sector so that such targets can be attained. The adjustment can be done through a set of instruments designed and optimized to attain such targets with minimum economic costs. This broader concept of internalization is widely followed by the European Union (EC, 2019).

Introduction

The value of time, more strictly the value of changes in travel time (VCTT), is a key economic concept in transport modeling and appraisal. Since many transport schemes and policies impact on travel time, the trade-off between travel time and money is of general relevance. The earliest treatment focused on “generalized cost,” which was defined as a linear combination of travel time and cost. However, while this is a convenient simplification and remains widely used, it is better seen as a reflection of the “indirect utility,” which is a feature of discrete choice models, and this has led to a more complex variation in the value of time.

While some exceptional forms of travel time may be seen as “pure leisure,” in general travel time is seen as conveying disutility, so that travelers will be willing to spend money to reduce it. In an indirect utility formulation, both travel time t and travel expenditure c will make negative contributions, and the value of time may be defined as the ratio of the partial derivatives of utility U to time and cost, so that $VCTT = \frac{\partial U / \partial t}{\partial U / \partial c}$. This formulation suggests that VCTT can vary with characteristics both of the journey (e.g., comfort) and of the individual (e.g., income).

Because of the importance of VCTT to transport appraisal, many countries have carried out value of time studies in order to inform “official” values. The earlier studies relied on revealed preference data, and required the researchers to find actual situations where travelers could be observed to trade between a faster, more expensive journey and a slower cheaper journey: these might be found with tolled bridge crossings, or express public transport services. In practice, the statistical requirements for successful studies of this kind are quite exacting, and most of these studies focused on the journey to work.

The development of stated preference (SP) techniques during the 1980s allowed the estimation of VCTT to be based on choices made between hypothetical alternatives, and, although there remain some reservations about the use of such data, all the most recent national studies have relied on SP. This has also allowed for much richer datasets and more detailed analysis of the variations in VCTT.

Microeconomic Theory—The Neoclassical Approach

The theoretical basis for time valuation is based on an expansion of the standard microeconomic demand analysis to include time as well as commodity prices. In this analysis, the individual’s total utility is expressed as a function both of quantity consumed and time expended, and this is maximized subject to various constraints, including a money budget and a time budget.

While a complete theory of time allocation would embrace all aspects of human behavior and as such would be quite unmanageable, it is necessary to make drastic simplifications, and the nature of these simplifications will affect the conclusions. Assume that an individual’s utility is a function of a vector of commodities $\mathbf{x}$, plus a vector of time spent in various activities, $\mathbf{t}$. One of these activities is assumed to be work, which for convenience is distinguished as t_w . This implies $U(\mathbf{x}, \mathbf{t}, t_w)$.

Various constraints are then introduced into the maximization problem. As budget constraints, the total expenditure ($\mathbf{p} \cdot \mathbf{x}$) cannot exceed the available income, which can be represented as $w \cdot t_w + \gamma$ where w is the wage rate (here assumed constant regardless of time worked, and, by implication, net of tax) and γ is the amount of income available from nonwork sources. In addition, the total time spent in activities cannot exceed the total time available, T . It would be possible to exclude from T certain essential requirements (e.g., sleeping, essential eating, etc.); note that the choice of T (24 h, say) implies certain units: for example, the amount of the income from other sources, γ , must be commensurate with the period assumed.

The standard assumption—that working hours are infinitely flexible, and can be freely varied by the consumer—is replaced by a slightly more realistic constraint—that it is necessary to work a minimum number of hours, t_w^* (again commensurate with the assumptions about T). Further, allowance is made for the fact that for certain activities (of which traveling to work is a good example), individuals are compelled to spend more time than they would ideally wish. Given the choice of period T , it is therefore assumed that each element t_i in the time vector has associated with it a minimum t_i^* (which may of course be zero); if required, these t_i^* could be taken as functions of further properties of the system, etc. Here, they act as exogenous constraints in exactly the same way as the minimum working hours hypothesis.

The model can thus be described as a maximization problem subject to a number of constraints, where, for clarification, the associated Lagrangian multiplier is included in square brackets after each constraint.

$$\begin{aligned} & \text{Max } U(\mathbf{x}, \mathbf{t}, t_w) \\ & \text{subject to} \\ & w \cdot t_w + \gamma \geq \mathbf{p} \cdot \mathbf{x} \quad [\lambda] \\ & T \geq \sum_i t_i + t_w \quad [\mu] \\ & t_w \geq t_w^* \quad [\phi] \\ & t_i \geq t_i^* \quad [\psi_i] \forall i \end{aligned}$$

An important distinction can be drawn between those activities for which the minimum time requirements are binding and those for which they are not. In the latter case, individuals are freely willing to commit more time to these activities than is strictly required. These activities can be referred to as “pure leisure activities,” with those activities where the time constraints do bind as “intermediate activities.” It is clear that with this definition, most types of traveling will be an intermediate activity. However, as we shall see, even in the case where travel is viewed as “pure leisure,” it will not lead to a negative value of time.

Formulating the Lagrangian as:

$$L = U(\mathbf{x}, \mathbf{t}, t_w) + \lambda \cdot (w \cdot t_w + \gamma - \mathbf{p} \cdot \mathbf{x}) + \mu \cdot \left(T - \sum_i t_i - t_w \right) + \phi \cdot (t_w - t_w^*) + \sum_i \psi_i \cdot (t_i - t_i^*)$$

the first order conditions for a maximum are obtained by differentiating with respect to $\mathbf{x}$, $\mathbf{t}$, and t_w (as well as the Lagrangian multipliers, which deliver the constraints), giving:

$$\begin{aligned} \partial U / \partial x_i - \lambda \cdot p_i &= 0 \\ \partial U / \partial t_j - \mu + \psi_j &= 0 \\ \partial U / \partial t_w + \lambda \cdot w - \mu + \phi &= 0 \end{aligned}$$

Defining the “marginal valuation of time spent in activity j ” as the ratio of the marginal utility of time in activity j to the marginal utility of income (λ), the second equation gives:

$$(\partial U / \partial t_j) / \lambda = \mu / \lambda - \psi_j / \lambda$$

When $\psi_j = 0$, because the time constraint does not bind, the marginal valuation of time in activity j is equal to μ / λ , the “resource value of time,” representing the consumer’s willingness to pay to have the total time budget increased (though a relaxation of the time budget constraint is not, of course, feasible in reality). Thus, for all “pure leisure” activities, the marginal valuation of time is equal to the resource value, at the optimum. This could either be because consumers are genuinely indifferent as to which leisure activity they are partaking of, implying a **constant** marginal valuation of time, or because they have rearranged their allocation of time to leisure activities so that the marginal valuations are all equal. In this latter case, there may be physical constraints (in space and time) or indivisibilities that impede such a rearrangement, so that the full value of leisure time cannot be realized. This “constrained transferability of time” is a difficult element to incorporate formally within the model, but it must be borne in mind.

While “pure leisure” time has a value (i.e., the “resource” value), in that utility is derived from it, there is no value, **at the margin**, to a **saving** in leisure time. Any time saved in one leisure activity can only be used in another leisure activity, and will have the same valuation. Thus, the consumer will not be prepared to pay to save (pure) leisure time, since he cannot increase his utility by so doing. This argument carries over, of course, to those types of travel that may be considered “pure leisure.”

For intermediate activities, however, the marginal valuation of time in the activity is less than the resource value, and indeed for most kinds of traveling will be negative. The difference between the marginal valuation of time spent in an intermediate activity i and the resource value is ψ_i / λ . By reducing the amount of time spent in activity i and transferring it to leisure, it is possible to increase utility by a unit amount equal to the difference between the marginal valuations of time spent in the activity and time spent in leisure. Hence, ψ_i / λ represents the value of saving time in activity i and transferring it to leisure, and it is this concept which is conventionally referred to as the “value of time” in transport appraisals.

That the marginal valuation of a certain kind of traveling time may be negative reflects directly that such time incurs disutility. But this is not a precondition for time savings having a value. Travel in certain conditions may be sufficiently comfortable that additional time is not directly viewed as a disbenefit. However, because of the overall constraint on time, the traveler can attain a greater total utility by transferring time from the travel activity to leisure. The only circumstance in which this will not be the case is where the travel itself is viewed as pure leisure (perhaps a Sunday drive in scenic surroundings). In this case, the constraint does not bind, so that ψ_i is zero.

Hence, the empirical interest is centered on the values of ψ_i / λ , and in terms of the theory set out here, these values are never negative, and are nonzero every time the consumer is forced to spend more time in an activity than he would ideally wish. The earlier equation can be rewritten to derive the fundamental property of time value:

Value of saving time in activity i (ψ_i / λ) = Resource value of time (μ / λ) – Marginal valuation of time spent in activity i ($(\partial U / \partial t_i) / \lambda$)

This implies that the VCTT could vary because of (1) the income of the individual (λ), (2) the extent to which the individual is time constrained (μ), and (3) the (marginal) utility of the time spent traveling ($\partial U / \partial t_i$), which will be affected by factors such as

comfort, and the opportunity to undertake other activities. In most transport problems, the marginal valuation of time is expected to be negative, because travel time contributes to disutility. However, recent technological developments (mobile phones, etc.) can be considered to have an important impact in reducing this disutility.

While this remains the generally accepted theory, it can be argued that it still lacks two other dimensions—possible variation in goods consumption through substitution of travel for other activities and the possibility of retiming activities (to deal with what was described earlier as the “constrained transferability of time”).

Further, while the economic theory outlined is strictly neoclassical in nature, there are further extensions that owe more to prospect theory and in particular the concept of “reference dependence.” This in turn leads to the phenomenon of “loss aversion” (essentially, a discontinuity in the derivative around the current “reference point”), as is discussed later.

Empirical Methods for Measuring Values of Time

In terms of empirical research, in the simplest case, respondents are asked to choose between two alternative journeys (A and B) with different costs C and times T . To avoid a “dominated” choice, the data should be such that if $C_A > C_B$, then $T_A < T_B$, and vice versa. The choice implies a “boundary value of time” (BVoT) = $-\frac{C_A - C_B}{T_A - T_B}$. If a respondent chooses the more expensive option, this implies that their VCTT > BVoT, and conversely. While there may be more than two choices, and/or the choices may be defined on more variables, the essential principles remain the same. The data are usually analyzed by discrete choice methods, and treated as a panel, since typically each respondent faces multiple choices.

There are two key issues relating to the analysis: the error specification and the utility specification. In relation to the error specification, illustrating the issue with the binary choice example just given, a conventional treatment would assume:

$$U_A = \lambda \cdot C_A + \psi \cdot T_A + \varepsilon_A, \quad U_B = \lambda \cdot C_B + \psi \cdot T_B + \varepsilon_B$$

for the conditional indirect utilities of the alternatives, where ε has the extreme value Type 1 (Gumbel) distribution, and VCTT = ψ/λ . This can also be rearranged in “difference form” as:

$$U_{A-B} = \lambda \cdot [(C_A - C_B) + \text{VCTT} \cdot (T_A - T_B)] + \eta, \quad U_0 = 0$$

where η has the logistic distribution (equivalent to the difference of two identically and independent Gumbel distributions).

However, it is also possible for the error term to be applied “multiplicatively” (or additive in the logarithms). Taking logs, after some rearrangement, we obtain:

$$U_{A-B} = \lambda' \cdot \ln \left[\left(-\frac{C_A - C_B}{T_A - T_B} \right) / \text{VCTT} \right] + \eta = \lambda' \cdot \ln [\text{BVoT}/\text{VCTT}] + \eta, \quad U_0 = 0$$

Some empirical work has found that this latter form provides a much better fit to the data.

In both cases, VCTT can be estimated as a function of appropriate covariates, as well as allowing it to have a random distribution.

The other notable complication for the analysis is the allowance for possible “sign and size effects,” which are present when the alternative choices are based on a status quo position. Respondents may value a reduction in travel time less than an increase (in line with prospect theory), and they may also have a lower unit value for small changes, which may not be seen as useful (or perceptible). Failure to allow for these “reference-dependent” effects could lead to biases and results which are overly dependent on the design of the SP.

One possible approach is to introduce nonlinear functions that allow for the possibility that size and sign effects exist, by defining a function for the *value* of a change Δx relative to the reference value x_0 of a given attribute. Since size and sign effects should be expected for both time and cost attributes, the impact on VCTT is not readily predictable. A suggested formulation for the value function is:

$$v(\Delta x) = \text{Sgn}(\Delta x) \cdot \exp(\omega \cdot \text{Sgn}(\Delta x)) \cdot |\Delta x|^\alpha$$

where

$$\begin{aligned} \Delta x &= x - x_0 \\ \alpha &= 1 - \beta - \gamma \cdot \text{Sgn}(\Delta x) \end{aligned}$$

$\text{Sgn}(\Delta x)$ is the sign function, defined for $\Delta x \neq 0$ by $\text{Sgn}(\Delta x) = \Delta x/|\Delta x|$.

ω measures the sign effect, giving the difference of gain value and loss value from an “underlying” value. It is expected that $\omega > 0$, so that the value of losses (increases in Δx) is greater than the value of gains.

β is the main measure of the size effect, allowing the impact of gains and losses to be nonlinear. If $\beta > 0$, the marginal value of changes decreases as the change increases, that is, the value is “damped” (noting the minus sign in the formula for α earlier).

γ allows for an interaction between the sign and size effects. For example, a negative value for γ (again noting the minus sign in the formula for α earlier) would mean that any damping (due to $\beta > 0$) would be smaller for increases (i.e., losses) than for decreases (i.e., gains) from the reference value.

The arguments of the value functions need to be defined in consistent units. While this is an arbitrary choice, it is sensible—given the interest in VCTT—to choose units of money, so that, if θ is the “underlying” value of time, the value of a cost change ΔC is given by $v(\Delta C)$, while the value of a time change ΔT is given by $v(\theta \cdot \Delta T)$. The resulting values calculated for v are in arbitrary units.

The value functions are assumed to be of the same general form for time and cost (and potentially for other utility components) but the parameters ω , β , and γ are specific to each utility component.

The presence of the sign function $\text{Sgn}(\Delta x)$ in the value formula introduces a discontinuity at the reference value, so that it is not appropriate to obtain VCTT from strictly marginal valuations, as would be found by differentiation. It is also a potential obstacle to its use in appraisal, as will be discussed later. Only if the parameters η and γ are zero for both time and cost, thus eliminating the discontinuity, can the formula $\text{VCTT} = \frac{\partial U}{\partial T} / \frac{\partial U}{\partial C}$ be used.

Instead, VCTT can be derived by thinking of the values of ΔC and ΔT that would maintain indifference with the base situation, where $\Delta C = \Delta T = 0$ and the total value $v(\Delta C) + v(\theta \cdot \Delta T)$ is zero. Thus, given a specific value $\Delta T'$, and the estimated parameters of the value functions v , the requirement is to find the value $\Delta C'$ such that $v(\Delta C') + v(\theta \cdot \Delta T') = 0$. The average willingness to pay per unit of time is then $\Delta C' / \Delta T'$.

In appraisal, and indeed other practical applications of VCTT, we will generally require a “reference free” value. By taking an average of the gain value and the loss value to express an “underlying” VCTT, the formulae can be simplified. For example, consider the geometric mean of $v(\Delta x)$ and $-v(-\Delta x)$:

$$\begin{aligned} & \sqrt{v(\Delta x) \cdot [-v(-\Delta x)]} \\ &= \sqrt{\left[\text{Sgn}(\Delta x) \cdot \exp(\omega \cdot \text{Sgn}(\Delta x)) \cdot |\Delta x|^{1-\beta-\gamma \cdot \text{Sgn}(\Delta x)} \right] \cdot \left[-\text{Sgn}(-\Delta x) \cdot \exp(\omega \cdot \text{Sgn}(-\Delta x)) \cdot |-\Delta x|^{1-\beta-\gamma \cdot \text{Sgn}(-\Delta x)} \right]} \\ &= \sqrt{\left[\exp(\omega \cdot \text{Sgn}(\Delta x)) \cdot |\Delta x|^{1-\beta-\gamma \cdot \text{Sgn}(\Delta x)} \right] \cdot \left[\exp(\omega \cdot \text{Sgn}(-\Delta x)) \cdot |-\Delta x|^{1-\beta-\gamma \cdot \text{Sgn}(-\Delta x)} \right]} \\ &= \sqrt{\exp(\omega \cdot [\text{Sgn}(\Delta x) + \text{Sgn}(-\Delta x)]) \cdot |\Delta x|^{1-\beta-\gamma \cdot \text{Sgn}(\Delta x) + 1-\beta-\gamma \cdot \text{Sgn}(-\Delta x)}} = |\Delta x|^{1-\beta} \end{aligned}$$

This gives a value which omits the asymmetry parameters ω and γ . However, there is no analogous argument by which β can be eliminated, so that a “size effect” may remain, with value being a function of Δx .

Using these simplified value functions $v(\Delta x) = \text{Sgn}(\Delta x) |\Delta x|^{1-\beta}$, the equation $v(\Delta C') + v(\theta \cdot \Delta T') = 0$ can be readily solved. For example, with negative $\Delta T'$ thus implying positive $\Delta C'$, the equation becomes:

$$(\Delta C')^{1-\beta_c} - (\theta \cdot |\Delta T'|)^{1-\beta_t} = 0$$

where

$$\Delta C' = (\theta \cdot |\Delta T'|)^{\frac{1-\beta_t}{1-\beta_c}}$$

This then yields $\text{VCTT} = \Delta C' / \Delta T' = (\theta)^{\frac{1-\beta_t}{1-\beta_c}} \cdot (|\Delta T'|)^{\frac{\beta_c - \beta_t}{1-\beta_c}}$. The same value is obtained if the signs of $\Delta T'$ and $\Delta C'$ are reversed.

If there is no size effect ($\beta = 0$) or the size effect is the same for both cost and time ($\beta_c = \beta_t$), then VCTT is independent of $\Delta T'$ and equal to the “underlying value” θ . However, in general the β values will not be zero and, given the expectation that β should be larger for cost than for time, VCTT will increase as the changes increase. This means that a decision is required for application in terms of what value of $\Delta T'$ is appropriate.

Key Findings

Empirical analysis has established certain key results. There is general agreement that VCTT increases with income, as would be predicted by the influence of λ , the marginal utility of income. There is also considerable evidence that VCTT increases with journey length, though the reasons for this are less clear: there is some empirical evidence that VCTT tends to increase with the journey cost, and decrease with the journey time (note that these are the opposite effects that might be expected on grounds of time and money budgets). Of course, both cost and time are expected to be positively associated with distance: the resulting association of VCTT with distance seems to be brought about by the cost effect being slightly larger than the time effect.

With regard to journey purpose, business journeys tend to have the highest VCTT (though in terms of application such values are often based directly on the wage rate), followed by commuting and then other leisure journeys. While a priori one might expect variation by travel mode to reflect different levels of comfort, conflicting results have been found. For a given mode, higher values tend to be found in conditions of congestion or crowding, but VCTT for the bus mode is typically lower than for rail, whereas on comfort grounds one would expect the opposite. It has been posited that this is due to income effects, but explicit attempts to take account of income do not affect the results materially. There may therefore be some “self-selection” issues, whereby individuals with low VCTT gravitate toward slower, cheaper modes and vice versa.

Individual studies have identified a number of plausible covariate effects, but there is no strong consistency between them. For example, VCTT for car users can be influenced by the number of passengers, but different datasets can suggest different directions.

Of course, pleasant passengers could be expected to reduce VCTT, while annoying passengers would increase VCTT. The “quality” of the passengers will not usually be known to the analyst.

There has also been recent interest in whether the VCTT associated with autonomous vehicles might be lower than that for conventional cars. There is some suggestion that this is the case, but the results need to be seen in the context of the difficulty in describing the experience of an autonomous vehicle to a respondent within an SP exercise.

In any event, after testing for the effect of all reasonable covariates, there remains a considerable random (unexplained) element in the VCTT distribution. Typically, a positively skewed distribution is found (such as the lognormal), suggesting some concentration in the lower values.

In application, a decision needs to be made as to how many of these variations should be included. In practice, relatively aggregate values are likely to be used (especially with regard to official recommendations for transport appraisal), and such values, being averages over a number of covariates, should be based on a representative sample of journeys (as might be obtained from a national travel survey).

Valuation of Carbon Emissions

The monetary value to assign to carbon emissions is an important question for many policy decisions. The focus of this chapter will be on the value to use in cost-benefit analyses (CBA) for transport infrastructure investments. We address a situation in which there is a target for carbon emissions now or in the future. This target may cover the transport sector only or a larger sector of which transportation is a part. The main message of this chapter is that the value to assign to carbon emissions in these CBAs should be derived from the target. However, the value will also be affected by which policy instruments are in place in order to reach the target. A number of caveats and complications will also be addressed.

A usual way to determine a value of a nonmarket effect to use in a CBA is to estimate the marginal damage the activity causes. For instance, in order to estimate the value of noise, one approach would be to use the price of sold houses and apply a hedonic approach to isolate the effect of noise exposure, see [Wilhelmsson \(2000\)](#) or [Andersson et al. \(2010\)](#). The corresponding approach for a value of carbon would be to calculate the damage associated with emitting one extra unit of carbon. Calculating this so-called social cost of carbon is a rather complex task, not least because it is the concentration of carbon dioxide (CO₂) in the atmosphere that matters for the greenhouse effect and CO₂ will remain in the atmosphere for a long time ([Bell and Callan, 2011](#); [Farmer et al., 2015](#); [Nordhaus, 2014, 2017](#)). Thus, the future trajectory of emissions must first be established and then the costs associated with shifting this trajectory up by one marginal unit can be calculated. Several studies have attempted to calculate the social cost of carbon and have ended up with quite a wide range of estimates ([Tol, 2009, 2019](#)).

Even if a good estimate of the social cost of carbon existed, I claim that it would have little relevance to the purposes discussed here. This is because once a climate policy is in place, infrastructure investment should be aligned with this policy. After all, the role of a CBA is to provide well-founded guidance for infrastructure investments. If there is a quantitative target for greenhouse gas emissions, the CBA must take into consideration the restrictions imposed by the target. The target will create an implicit price for CO₂ emissions, a shadow price, and this price is what should be reflected in the CBA, see [Mandell \(2011, 2013\)](#) and [Isacs et al. \(2016\)](#). We will return to this below.

I will use the Swedish case as a base for the discussion. Sweden serves as an interesting example as it has one of the world's most ambitious climate targets and has a relatively long history of climate policy. Even if Sweden's climate policy differs from many other countries, the reason for not adopting the social cost of carbon applies almost universally as basically all countries have ratified the Paris Agreement. Thus, they must decide on Nationally Determined Contributions (NDCs). Therein, each country specifies how it intends to contribute to the overarching goal of the Paris Agreement—to keep temperature rise well below 2°C with a goal of 1.5°C. NDCs come in different forms, see [Denison et al. \(2019\)](#) and King and van den Bergh (2019). Roughly one-third of the countries set economy-wide reduction targets in relation to a specific base year. Almost one half set relative targets to reduce emissions below business-as-usual levels. A few countries set intensity targets that relate greenhouse gas (GHG) reductions to gross domestic product. Around one-fifth of the countries have included strategies, plans and actions for low GHG emissions development ([UNFCCC, 2016](#)). How the NDC is formulated matters, but basically, once a country has decided on a target—absolute or relative—the policy challenge it faces is how to reach that target.

Sweden implemented a CO₂ tax in 1991, making it one of the first countries to do so (Finland and the Netherlands introduced CO₂ taxes in 1990). Presently, around 30 other countries have CO₂ taxes in place or are planning to introduce them soon ([World Bank, 2019](#)). Currently, Sweden has the world's highest CO₂ tax. When it was introduced in 1991 it corresponded to approximately EUR 25 per ton (fossil) CO₂. In 2019, the CO₂ tax amounted to EUR 118 per ton (fossil) CO₂. In real terms, this corresponds to an increase just above a factor three since the introduction of the tax.

The main rule in Sweden is that CO₂ tax is levied on all activity that is not subject to the EU's Emissions Trading Scheme, EU ETS, even if various forms of tax deductions apply. As the discussion here is limited to CBAs for transport infrastructure investments, our focus is on the transport sector. Apart from the CO₂ tax, there is also an energy tax and VAT levied on fuel. The CO₂ tax is proportional to the fossil fuel content of the fuel in question. However, the energy tax is not proportional to the energy content. This is understandable as the stated purpose of the CO₂ tax is to handle CO₂ emissions whereas the stated purpose of the energy tax is broader. Initially, its purpose was mainly fiscal but over time it has become increasingly viewed as the primary tool for internalizing externalities not handled by other instruments.

The CO₂ tax and the energy tax increase annually with the consumer price index and an additional 2% so as not to erode the pressure of the taxes as the economy grows and people get richer. In addition to the CO₂ tax and the energy tax is a series of other policy instruments which, in various ways, influence CO₂ emissions from the transport sector. These include a CO₂-differentiated vehicle tax, subsidies for low-emission cars, etc. Nevertheless, the main instrument has arguably been the CO₂ tax on fuel. As indicated below, recent reforms have changed this.

In Sweden, the values to use in CBAs for CO₂ emissions, as well as all other externalities from transport activities that are handled in the analyses, are based on recommendations from a working group known as ASEK. The recommendations are updated annually although major revisions occur at around 3- to 4-year intervals.

To date, six versions of ASEK recommendations have been published. In several of the recommendations, the CO₂ tax is used as a proxy for the CO₂ value. The stated rationale is that the CO₂ tax could be viewed as revealing the value politicians place on reducing emissions by one unit, that is, how much politicians believe society would be willing to sacrifice in order to reduce emissions.

The second version of the ASEK recommendations, published in 1998, contains a different argument. At the time, Sweden had implemented an emission target specific to the transport sector stating that until 2010 it should reduce its emissions to the level it showed in 1990. Rather than basing the CO₂ value on the CO₂ tax, ASEK argued that the value should reflect the shadow price resulting from the target. The rationale remains similar: the CO₂ value should be derived from policy and reflect a “political” value, c. f. Sager (2013). However, as the CO₂ tax was probably not high enough for the transport sector to reach the target, ASEK set out to answer the following question: what CO₂ tax would be needed in order to meet the target?

In short, the approach applied to answering this question involved studying three effects of an increased CO₂ tax: less kilometres travelled, changed driving behavior (eco-driving), and a shift to more energy-efficient vehicles. The responsiveness of each effect to changes in the CO₂ tax was estimated along with how significant an impact each effect was likely to have on reducing emissions.

The analyses resulted in the CO₂ value being increased considerably, from approximately EUR 38 per ton CO₂ to around EUR 150. This value was retained in the subsequent recommendations. When it was time to release the fourth version of the recommendations, it was apparent that the target would not be met. However, as no new target had been set, ASEK opted to keep a CO₂ value of EUR 150 per ton. In the fifth version, ASEK reverted to using the CO₂ tax as a valuation and consequently reduced the value from EUR 150 to EUR 108 per ton. Applying a value corresponding to the CO₂ tax is also the recommendation in the most recent sixth revision.

Thus, the current Swedish approach is to use the value of the CO₂ tax as a kind of political revealed preference. This approach clearly has some merits. The value used in the CBA must be aligned with the climate policy—otherwise the CBA recommendations will not correspond with the needs created by the policy which, in turn, may lead to construction choices that are not well founded. In a simple world in which CO₂ tax is the only climate policy instrument and in which the tax is intended to handle climate issues only (i.e., it is not calibrated to also handle other co-benefits), it should serve as a valid CO₂ value in the CBA as long as it is set in such a way that the target is reached.

In Sweden, the CO₂ tax has never been the only climate policy instrument. However, it has arguably been the most important instrument—and the approach of using it as a proxy for the CO₂ value seems justifiable. If nothing else, it has been a transparent strategy.

However, a series of recent reforms to Swedish climate policy has changed this. Of particular importance to our discussion is a new target for CO₂ emissions from the transport sector and the implementation of a CO₂ emissions reduction obligation. The transport sector goal, adopted in 2017, states that by 2030 the Swedish transport sector—not including aviation, which is covered by the EU ETS—should have reduced its CO₂ emissions by 70% compared to 2010. In 2018, Sweden introduced a CO₂ emissions reduction obligation for transport fuels. It feeds biofuels into the fuel mix. This was previously handled by differentiated CO₂ and energy taxes to the extent that taxes on biofuels were kept sufficiently low for them to be economically viable alternatives to fossil fuels. However, this approach did not work well with EU legislation and required exemptions. It was therefore abandoned.

Both these reforms imply that the principle of applying CO₂ as a proxy for a CO₂ value in the CBA has become obsolete, but for slightly different reasons. First, the new transport sector target will probably not be reached given the CO₂ tax, even considering the annual indexation. Second, the reduction obligation changes the functioning of the CO₂ tax. The tax will still influence car usage, vehicle choice, etc., but will no longer influence the fuel mix. This is now handled by the reduction obligation. Thus, the CO₂ tax has lost one of its purposes.

As the previous approach of using CO₂ tax as a proxy for an appropriate CO₂ valuation is no longer applicable, an alternative approach is needed. The approach we will pursue here is something that is in line with what ASEK did in 1998, that is, start with an estimate of the shadow price that results from the target. There are several ways of estimating the shadow price, for example, applying a computable general equilibrium (CGE) model to calculate what CO₂ tax would be required for the transport sector target to be met by 2030. There are a number of technical problems with such an approach but we will not address these here. Rather, let us assume that we have a model capable of estimating what tax would be required to reach the target. Given this, what issues must be clarified before we apply it?

One obvious issue is to clarify the measure we are really interested in. Above, and in line with how ASEK phrases it, we state that the CO₂ tax was applicable as it gives a proxy for a political valuation. This suggests that we are looking for a measure of how many other resources society is willing to give up in order to reduce CO₂ emissions by one unit. This is clearly an interesting figure. However, given the new policy, I would argue that it is not necessarily what should be used in the CBA as a CO₂ value.

To see this, let us take as a fact that a quantitative emissions target is to be fulfilled at a specified future point in time—in a Swedish context, minus 70% by 2030. Now consider an infrastructure project, say a new road, which is projected to increase CO₂ emissions *ceteris paribus* by one unit. The CO₂ value should be a measure of the societal cost of this extra unit.

First, it should be noted that this cost has nothing to do with climate. The target is to be met with or without this project, so CO₂ emissions will remain the same. Consequently, if there is an additional unit of CO₂ emissions stemming from this project, there must be a corresponding reduction by one unit somewhere else or the target will be breached. It is the cost of achieving this one unit reduction somewhere else that should be the CO₂ value, that is, we adopt an opportunity cost approach.

Second, the relevant CO₂ value has nothing to do with the “political valuation” more than in an indirect sense. The emission target is a consequence of political decisions, but once it is in place it is the opportunity cost it creates that is of interest. This distinction is of little concern if the instrument used to reach the target is a CO₂ tax only. However, consider a situation in which two policy instruments are used: a CO₂ tax on fuel and subsidies for energy-efficient vehicles. In order for the CO₂ value to capture the political valuation, it should consider both the CO₂ tax and the subsidies, as both are associated with costs to society. However, if the CO₂ value is to capture the opportunity cost in the sense discussed above, it should only consider the CO₂ tax. If the government subsidizes energy-efficient vehicles, the applicable CO₂ value will be less than if there were no subsidies. This is because subsidies will make it easier and less costly for society to reduce emissions somewhere else in such a way that the target is still met. In this case, the political valuation—which includes the costs associated with subsidizing energy-efficient vehicles—will exceed the relevant opportunity cost—which only includes the variable cost.

In this view, not only do we need to consider the target and the shadow price in which it results. We also need to take into account what policy mix will be used to reach it. This makes the task more complicated. Even so, the outcome is in line with the purpose of the CBA—to help policymakers choose which transport infrastructure to invest in. To illustrate using a crude example, consider two alternative policy packages that reach the same emission target at some future point in time. One package relies on CO₂ taxes only. In order to reach the target, these taxes must be high, thus making it costly to travel by car. Demand for car travel therefore drops. In such a situation, spending resources on, for example, new roads may be less desirable. The other policy package combines CO₂ taxes with large subsidies for energy-efficient vehicles. The CO₂ tax required to reach the target is now lower than without the subsidies and the cost of travelling by car is consequently lower compared to the alternative policy package. In this situation, new roads may be more desirable as demand for road transport will be higher and the negative effects of CO₂ emissions will be less. Thus, in order to provide guidance on what to invest, the CBA—through the CO₂ value—must consider the policy design, not only the target.

There are several other complicating factors. One of these concerns whether it is correct to view the target as given. After all, targets are not always met. As discussed above, Sweden previously had a target for the transport sector that was abandoned. This target resulted in the CO₂ value being increased quite substantially. Thus, for a period, the CBAs calculated on a future that did not emerge, thereby resulting in erroneous recommendations. However, ignoring a politically determined target does not appear to provide a basis for well-founded analyses.

A related issue is that the arguments above rely on the idea that the CO₂ value should be derived from the adopted climate policy. But what if infrastructure investments form part of that policy package? For example, some may consider investments in railways in order to provide substitutes for less climate-friendly alternatives, such as climate policy measures. We may view this in two ways: either we invest in railways to save the climate or, when we try to save the climate, demand for climate-friendly alternatives will increase and we then need to construct more railways. If we adopt the latter view, the above arguments apply. However, if we adopt the former view, the measure we are assessing itself becomes part of the policy package. The basic problem is that if infrastructure investments are considered part of climate policy, constructing a project should entail calibrating other climate policy measures, for example, the CO₂ tax, so that emissions are kept at the target level. One way of reconciling this is to view individual projects as being too small to justify such calibrations as anything but negligible (i.e., an assumption akin to that, in the perfect competition model, no individual firm is large enough to influence price).

Thus far, we have argued that a valid CO₂ value should be based on the target if such a target exists and that we must also consider what policy measures are employed in order to reach the target. As policy design must also be taken into consideration, we must also consider the policy’s purpose. It is often claimed that climate policy is associated with substantial co-benefits, including less congestion and better air quality, as well as more jobs, more competitive businesses, etc. To the extent that such co-benefits exist, we would not want them to end up in a CO₂ value as they concern issues other than CO₂ emissions. The CBA should capture all relevant effects, but the effects should not be attributed to climate if they concern other aspects. Given the opportunity cost approach outlined above, this problem may largely disappear as it relies on the shadow price of the CO₂ target.

Another complication lies in the cost effectiveness of the actual policy mix. The approach here is to start by calculating the shadow price resulting from the target. This corresponds to calculating how large a CO₂ tax must be in order to reach the target, given that no other policy measures are being used. We have then argued that if the actual (anticipated) policy mix contains instruments that influence the opportunity cost, these should be taken into consideration. The problem is that the least costly way to reach a CO₂ emissions target is to assign a uniform price for emissions, for example, by using a uniform CO₂ tax. Thus, a policy mix that also includes other measures will increase costs. In principle, this should influence the CO₂ value. After all, we have argued that it is the opportunity cost to keep emissions at the target level that matters. If the policy is designed in a nonoptimal way, in such a way that the opportunity cost becomes higher, the CO₂ value should address this. At the same time, it will probably make it more difficult to calculate the shadow price.

The fundamental driver behind the discussion above is that the CO₂ value should take its departure in the target and the policy mix that is used to reach it. If there are several different targets covering different parts of the economy, this may generate counterintuitive outcomes.

The most obvious example is a discrepancy between the value of CO₂ emissions that occur during infrastructure construction versus emissions that occur when the infrastructure is in use. We have argued that the value to associate with the latter follows from the costs associated with having to change behavior somewhere else under the transport sector target in such a way that the target is still met. A similar argument should apply to emissions associated with construction. However, to a large extent, such emissions, for example, emissions from steel and cement production, fall under a different target, given by the EU ETS. Thus, the corresponding logic states that these emissions should be valued at the shadow price generated by the ETS. The allowance price would appear to be a

good candidate. In the Swedish case, this would imply a much lower valuation of CO₂ emissions occurring during the infrastructure construction phase than those emissions that occur from using the same.

This creates something of a problem. Consider two alternative projects: A and B. They are identical in every way except that A is associated with lower CO₂ emissions in the usage phase and higher emissions associated with construction in such a way that total emissions would be higher from project A than project B. Climate is affected in the same way regardless of whether the emissions stem from construction or usage. So, from a climate perspective, project B would appear to be preferable. However, if the CBA applies a higher CO₂ value to emissions that result from usage rather than from construction, the analyses may result in the opposite recommendations. This may seem counterintuitive. Even so, it is in line with the underlying logic that, if we accept the notion that targets should be met, the CO₂ value has nothing to do with climate. It is only driven by how the costs of reaching the targets in question are influenced by the project under study. Thus, total emissions are not influenced by whether project A or B is chosen (as both the emissions from construction and usage are subject to targets). However, the cost of reaching the targets differs between projects and a well-designed CBA should capture these differences.

A similar example considers the electrification of transport. This may take the form of constructing infrastructure in such a way that traffic shifts from road to (electrified) rail transport, or stems from major electrification of the car fleet. In both cases, emissions will most probably be reduced but will also “move” from the ESR sector, which covers emissions from transportation, to the EU ETS sector, which covers emissions from the generation of electricity. The problem is the same. A lower value should be attached to emissions under the EU ETS than those under ESR to reflect the difference in opportunity cost, even though the emissions have the same impact on climate. Again, this is due to both the ETS and the ESR being subject to targets in such a way that the climate is left unaffected. However, the (marginal) cost of reaching the targets differ between sectors, and this should be captured by the CO₂ values in the CBA. It should be noted that a recent reform of the EU ETS implies that emissions from the system are, to some extent, endogenous (Carlén et al., 2019). This complicates the question of how to view the EU ETS target but should not fundamentally change the arguments put forward here.

To summarize, in this chapter I have argued that it is important that the CO₂ value used in CBAs for transport infrastructure captures the societal costs associated with CO₂ emissions. However, if there is a binding emissions target, this cost is not associated with climate (as the target implies that emissions will be the same whether or not the project is subject to the CBA) but rather with how infrastructure construction influences the costs of reaching such a target. This perspective introduces a series of interesting questions and problems, some of which have been discussed above.

The Concept of Travel Time Variability

The travel time for a journey from A to B with a given transport mode can vary for many different reasons. Some of this variation can be anticipated by the travelers: The travel time may be longer on a Monday morning during the peak hours than on a Sunday evening, due to different levels of congestion in the network. However, some variation is unpredictable for the traveler, for instance the day-to-day variation for a trip carried out every weekday at the same time of day under seemingly identical circumstances. We refer to this unpredictable variation as travel time variability (TTV).

TTV may arise due to fluctuations in traffic demand from day to day, which are random from the travelers' point of view, or due to traffic incidents, transitory roadworks or unanticipated harsh weather conditions affecting travel speeds and road capacity. TTV is costly for the travelers, since the unpredictability causes people to either risk arriving later than desired, or to depart sufficiently early to allow for a safety margin to avoid being late, potentially wasting their time. As a cost for the travelers, TTV should in principle be accounted for, both when predicting demand in transport models and when evaluating transport and infrastructure projects in cost-benefit analyses, in order to incorporate effects of changed TTV along with effects of changes in average travel times. This requires that we know the following:

1. how to appropriately measure TTV (i.e., should we use the standard deviation of travel time, the mean delay or another measure of variability to quantify the extent of TTV?);
2. how TTV affects behavior in terms of departure time, mode, and route choice;
3. the monetary value of TTV; and
4. how to predict TTV for various scenarios.

The topic of this chapter is the theoretical foundation for (1)–(3). Two approaches coexist in the transport economic literature: One is the scheduling approach, assuming travelers derive utility from spending time in certain activities at certain times of day, and that TTV affects their expected utility through its impact on the arrival times at the activities. The other is the direct approach, which ignores the scheduling aspect and simply assumes that travelers incur a cost from TTV, whether it may stem from scheduling inconvenience or anxiety. The early literature dates back to the 1960s, and particularly the scheduling approach has developed over time with several extensions and adaptations. We do not provide a review of this literature here, but refer to the list of further readings, which contains a comprehensive review of the use of the two approaches (Carrion and Levinson, 2012), as well as research articles with recent methodological advances. For a review of the literature related to forecasting TTV for appraisal (4), we refer to de Jong and Bliemer (2015).

Here, we will present a simple scheduling model as the basic microeconomic framework for valuing TTV, based on Fosgerau and Karlström (2010), Fosgerau and Engelson (2011), and Fosgerau (2016).

Microeconomic Foundation: A Simple Scheduling Model

The General Framework

A scheduling model describes travelers' preferences for being at different locations at a given time, and for transporting themselves at a given time. Most scheduling models in the literature are partial models that only consider the problem of choosing the optimal departure time on a given journey, and take as given the travelers' preferences for being at the origin and destination. It is assumed that the departure time can be chosen continuously. Moreover, many models are pure demand-side models, taking the distribution of travel time as given and thus ignoring that travelers' choices of departure times affect the distribution. Finally, it is common to consider the mode and route choice as given, but in principle the model can be extended to allow several modes and routes.

Our simple model embodies all these restrictions. Later, we discuss what happens if some of these restrictions are relaxed. Consider a traveler having a specific origin and destination (we can think of them as home and work), between which he desires to travel during a specified period of the day. We assume that the traveler is equipped with scheduling preferences, that is, preferences for being at the origin and destination at a given time, and that he chooses his departure time to maximize his expected utility. Moreover, we assume he considers only a single mode of transport and a single route, with a given (known) distribution of travel times.

We formalize this as follows: Let $[t_{start}, t_{end}]$ be the time interval, during which the traveler wants to travel. Define $h(t)$ as the marginal utility of being at the origin minus the marginal utility of time spent traveling at time t , and define $w(t)$ as the marginal utility of being at the destination minus the marginal utility of time spent traveling at time t . Assume $h(t)$ and $w(t)$ are monotonic and bounded on $[t_{start}, t_{end}]$: $h(t)$ is weakly decreasing and $w(t)$ weakly increasing. With these definitions and assumptions, the integrals $\int_a^b h(t)dt$ and $\int_a^b w(t)dt$ are well defined for $a, b \in [t_{start}, t_{end}]$. $\int_a^b h(t)dt$ is the excess utility from being at the origin in the time period $[a, b]$ compared to being traveling. Similarly, $\int_a^b w(t)dt$ is the excess utility from being at the destination compared to traveling. Assume further, that there is a time $t_0 \in [t_{start}, t_{end}]$ such that $h(t) > w(t)$ for $t < t_0$, and $h(t) < w(t)$ for $t > t_0$. Then the traveler prefers to be at the origin before t_0 and at the destination after t_0 . This idea is expressed graphically in Fig. 1. We also need a technical assumption to ensure the interval $[t_{start}, t_{end}]$ is wide enough to include the relevant departure and arrival times.

The traveler's scheduling utility, U , is assumed to be additively separable in the total utility obtained at the origin and the total utility obtained at the destination. For departure time t_d and a specific realization of travel time T , we have:

$$U(t_d, T) = \int_{t_{start}}^{t_d} h(t)dt + \int_{t_d+T}^{t_{end}} w(t)dt. \quad (1)$$

This is a general model that accommodates a variety of specifications of $h(t)$ and $w(t)$, corresponding to different assumptions about the scheduling preferences. We shall discuss two specific popular specifications in more detail below. Note that the function in Eq. (1) can be normalized in different ways to ease computations, corresponding to scaling or shifting the utility function.

We assume that travel time T is an absolutely continuous random variable with some distribution known by the traveler, and that the traveler chooses the departure time that maximizes his expected utility $EU(t_d) \equiv E[U(t_d, T)]$. We make the following assumptions about the distribution of T :

- the mean and variance of T exist;
- T has bounded support;
- the distribution of T does not depend on the departure time.

Figure 1 Marginal utilities of time spent at home and at the destination and time spent traveling.

Engelson and Fosgerau (2011) have shown that these assumptions imply that $EU(t_d)$ is concave, finite, and continuous in t_d , and that there exists an optimal departure time which maximizes $EU(t_d)$. Note that they define the traveler's departure time choice in terms of a cost minimization problem, where the cost function is equal to a constant minus $EU(t_d)$.

The assumption that T has bounded support means that we can define an interval $[t_{start}, t_{end}]$ that contains all possible departure and arrival times. This corresponds to reality, where the set of possible travel times is bounded. For modeling purposes, it may be relevant to consider cases where T does not have bounded support, such as the shifted exponential or lognormal distributions. The interested reader may consult Engelson and Fosgerau (2011) about conditions for existence of an optimal departure time in this case.

To formalize the link between scheduling costs and TTV, it is convenient to apply the decomposition $T = \sigma X + \mu$, where μ and σ are the mean and standard deviation of T , and X is a continuous random variable with zero mean and variance equal to 1. X has bounded support, and has a continuous density function ϕ . Moreover, we assume that X has an invertible distribution function Φ , such that the quantiles of the travel time distribution are uniquely defined. It is possible to assume specific distributional forms of X , if one has specific knowledge about this, but this assumption is not necessary, so we proceed without.

The assumption that the distribution of T does not depend on the departure time means both that the distribution of X does not vary over $[t_{start}, t_{end}]$ (which, according to some empirical evidence, may be acceptable as an approximation to reality), and also that μ and σ do not vary over $[t_{start}, t_{end}]$. This latter invariance assumption is restrictive, and almost certainly incorrect if $[t_{start}, t_{end}]$ includes both a congested peak period and the periods immediately before or after. We shall proceed using the invariance assumption because it provides simple and easily interpretable results, and because Fosgerau and Karlström (2010) have demonstrated, in the special case called the step model, c.f. below, that these results still hold approximately if μ and σ are linear functions of time, as long as they do not change too rapidly over time. We return to the implications of the invariance assumption in the third section.

The expected utility can be written as:

$$\begin{aligned} EU(t_d) &= \int_{t_{start}}^{t_d} h(t) dt + E\left(\int_{t_d+T}^{t_{end}} w(t) dt\right) \\ &= \int_{t_{start}}^{t_d} h(t) dt + \int\left(\int_{t_d+\mu+\sigma x}^{t_{end}} w(t) dt\right) \phi(x) dx. \end{aligned} \quad (2)$$

When $h(t)$ and $w(t)$ are continuous, $EU(t_d)$ is continuously differentiable in departure time t_d , and the unique optimal departure time t_d^* is defined by the first-order condition

$$\frac{\partial EU}{\partial t_d} = 0 \Leftrightarrow h(t_d^*) = E(w(t_d^* + T)). \quad (3)$$

For specific simple functional forms of $h(t)$ and $w(t)$, the optimal expected utility $EU^* \equiv EU(t_d^*)$ has a closed form. In that case, we can obtain VTT, the value of travel time (in utility units), as minus the derivative of EU^* with respect to μ , and VTTV, the value of TTV (in utility units), as minus the derivative of EU^* with respect to σ , σ^2 or another measure of the extent of variability in the travel time distribution.

We now take a closer look at two popular scheduling models, the step model and the slope model.

The Step Model

In the step model, $h(t)$ is a constant function equal to α , and $w(t)$ is a piece-wise constant function equal to $\alpha - \beta$ for $t < t_0$ and $\alpha + \gamma$ for $t > t_0$. The parameters α, β, γ are assumed to be positive. This type of preferences is widely used in applications and often referred to as α - β - γ -preferences. In this case, the utility function in Eq. (1) becomes

$$\begin{aligned} U(t_d, T) &= -\alpha T - \beta(t_0 - t_d - T)^+ - \gamma(t_d + T - t_0)^+ + K_1 \\ &= -(\alpha - \beta)T + \beta(t_d - t_0) - (\beta + \gamma)(t_d + T - t_0)^+ + K_1, \end{aligned} \quad (4)$$

where $z^+ \equiv \max(z, 0)$ and K_1 is a constant term which depends on $\alpha, \gamma, t_0, t_{start}$ and t_{end} . For a given value of T , this utility function is piecewise linear in t_d with a unique maximum in $t_d^* = t_0 - T$. Hence, in the case without TTV, where travel time is always equal to μ , the optimal departure time would be $t_0 - \mu$ with corresponding arrival time t_0 . When travel time is random, we assume the traveler maximizes his expected utility:

$$\begin{aligned} EU(t_d) &= -(\alpha - \beta)\mu + \beta(t_d - t_0) \\ &\quad - (\beta + \gamma) \int_{t_0 - t_d - \mu}^{\infty} (t_d + \mu + \sigma x - t_0) \phi(x) dx + K_1 \end{aligned} \quad (5)$$

Note that the integral on the right hand side is differentiable in t_d because the integrand is continuous in x and continuously differentiable in t_d , and the lower limit is continuously differentiable in t_d . The expected utility is twice continuously differentiable and strictly concave in t_d (as the second-order derivative is negative). The optimal departure time satisfies the first order condition $\frac{\partial EU}{\partial t_d} = 0$, which is equivalent to

$$t_d^* = t_0 - \mu - \sigma \Phi^{-1}\left(\frac{\gamma}{\beta + \gamma}\right), \quad (6)$$

where Φ is the distribution function of X . We see that the optimal departure time is linear in μ and σ , and depends on the distribution of X . The traveler departs earlier than in the case with certain travel time, by a safety margin $\sigma\Phi^{-1}[\gamma/(\beta + \gamma)]$. This safety margin is proportional to the standard deviation of travel time, and depends on the shape of the travel time distribution through Φ^{-1} . Naturally, it depends on the preferences for arriving earlier or later than t_0 : A higher value of γ (= a higher disutility of arriving later than t_0) implies an earlier optimal departure time. Departing at t_d^* , the traveller has probability $\frac{\beta}{\beta + \gamma}$ to arrive later than t_0 . Inserting the optimal departure time in Eq. (6) into Eq. (5) yields the following optimal expected utility:

$$\begin{aligned} EU^* &= -\alpha\mu - (\beta + \gamma)\sigma \int_{\Phi^{-1}\left(\frac{\gamma}{\beta + \gamma}\right)}^{\infty} x\phi(x)dx + K_1 \\ &= -\alpha\mu - (\beta + \gamma)\sigma \int_{\frac{\gamma}{\beta + \gamma}}^1 \frac{\gamma}{\beta + \gamma} \Phi^{-1}(s)ds + K_1. \end{aligned} \quad (7)$$

The second equality follows from applying the transformation $s = \Phi(x)$. This expression shows that the cost imposed by TTV depends on σ , the preference parameters, and the shape of the travel time distribution. Given Eq. (7), Fosgerau and Karlström (2010) suggest to measure the extent of TTV by σ , and the value of TTV (in utility units) as

$$VTTV = -\frac{\partial EU^*}{\partial \sigma} = (\beta + \gamma) \int_{\frac{\gamma}{\beta + \gamma}}^1 \Phi^{-1}(s)ds. \quad (8)$$

This value can be converted to a monetary unit by dividing with the marginal utility of income. As noted by Fosgerau (2016), the model also supports other choices of a measure of the TTV: The interquantile range of the travel time distribution, that is, the difference between two specific quantiles T_{p_2} and T_{p_1} , is often applied in the literature as a measure of TTV, and is equal to $IQR = \sigma[\Phi^{-1}(p_2) - \Phi^{-1}(p_1)]$ and hence proportional to σ , since we consider the distribution of X as fixed. Hence, Eq. (7) can be rewritten in terms of IQR , and the value of TTV can be defined in terms of $\partial EU^* / \partial IQR$. The same holds for the difference between a specific quantile and μ .

Another option, suggested by Small (2012), would be to measure TTV by $Q \equiv \sigma \int_{\frac{\gamma}{\beta + \gamma}}^1 \Phi^{-1}(s)ds$. Since the difference between the p -quantile of the travel time distribution and the mean equals $\sigma\Phi^{-1}(p)$, the quantity Q is an average over such differences for all values of p larger than $\gamma/(\beta + \gamma)$. Hence, Q is a generalization of a commonly applied measure of TTV, the difference between a specific quantile and μ . The VTTV corresponding to Q is $-(\partial EU^* / \partial Q) = \beta + \gamma$.

The first measures (σ and IQR) have the benefit that they are easy to compute and interpret; however the associated values depend on Φ and are hence not transferable from one application to another. For the second measure (Q), the opposite applies; and TTV itself depends on the preference parameters, such that it is not transferable from one group of travelers to another.

The Slope Model

In the slope model, $h(t)$ and $w(t)$ are linear functions intersecting at $t = t_0$: $h(t) = a + b(t - t_0)$ and $w(t) = a + g(t - t_0)$, where $b \leq 0$, $g \geq 0$, and $b < g$.

In this model, $h(t)$ and $w(t)$ are twice continuously differentiable, $EU(t_d)$ is strictly concave in departure time t_d , and there exists a unique optimal departure time t_d^* . This optimal departure time satisfies the first-order condition $\frac{\partial EU}{\partial t_d} = 0$, that is,

$$h(t_d^*) = E(w(t_d^* + T)) \Leftrightarrow t_d^* = t_0 - \frac{g}{g - b}\mu. \quad (9)$$

Unlike in the step model, the optimal departure time depends only on the mean travel time, and not on the level of TTV. This is a special property of the slope model, which follows from the linearity of $h(t)$ and $w(t)$. The optimal expected utility is:

$$\begin{aligned} EU^* &= \int_{t_{start}}^{t_0 - \mu \frac{g}{g - b}} \frac{g}{g - b} (a + b(t - t_0))dt + E\left(\int_{t_0 - \mu \frac{g}{g - b} + T}^{t_{end}} \frac{g}{g - b} (a + g(t - t_0))dt\right) \\ &= -a\mu + \frac{bg}{2(g - b)}\mu^2 - \frac{g}{2}\sigma^2 + K_2, \end{aligned} \quad (10)$$

which implies that the cost imposed by TTV is proportional to the variance of travel time, σ^2 , and depends only on σ^2 and the preference parameters. The constant term K_2 depends on t_0 , t_{start} , t_{end} , and on a , b , g , but not on the travel time distribution. Given Eq. (10), Fosgerau and Engelson (2011) suggest it is natural to measure the extent of TTV by σ^2 , and the value of TTV (in utility units) as

$$VTTV = -\frac{\partial EU^*}{\partial \sigma^2} = \frac{g}{2}. \quad (11)$$

Other Specifications

The step model and the slope model have the benefit that they yield closed-form expressions for the optimal expected utility and simple measures and values of TTV. However, it remains to be verified empirically how well the models represent traveler preferences. In principle there are many possible formulations of $h(t)$ and $w(t)$, but apart from the step model and the slope model, only a few have been applied in practice. Models with exponential functions also yield closed form solutions, but appear difficult to apply in practice, since the model parameters can be hard to identify from empirical data ([Hjorth et al., 2015](#)).

Extensions of the Simple Model

In this section, we briefly mention a couple of relevant extensions to the simple model. The interested reader is referred to the original research articles, provided in the literature list.

Imperfect Information or Limited Rationality

We have so far assumed that the traveler knows the travel time distribution and optimizes his expected utility. But how are the results affected if this is not the case? Generally, if the traveler has a wrong perception of the travel time distribution, it leads to suboptimal departure time choices, but the size of the additional cost, in terms of his utility loss, depends both on the nature of the misperception and on the assumed scheduling model.

Misperception could take the form of probability weighting, where the traveler systematically misperceives the probabilities of different travel time outcomes. Systematic probability misperception is consistent with observed behavior in many laboratory experiments regarding other types of random outcomes, and can be formalized using a rank-dependent utility model instead of assuming expected utility optimizing behavior. Applying a rank-dependent utility approach to the scheduling model is one way of deriving the cost of misperception: For both the step model and the slope model, [Xiao and Fukuda \(2015\)](#) have shown formally that this type of misperception implies a higher perceived cost of TTV.

Another form of misperception could be that the traveler forms his expectation about the travel time distribution partly based on a fixed perception of travel time, a so-called anchor value, and partly based on his experience of the last K trips, which he may not always remember or remembers inaccurately. [Koster et al. \(2015\)](#) have shown (for the slope model) that this may lead to suboptimal departure time choices and to a higher perceived value of TTV.

Scheduled Services

The assumption that departure time choice is continuous may at first glance seem to restrict the model to private modes of transport (cars, bikes, etc.). However, the approach can be extended to cover scheduled services as well. [Fosgerau and Karlström \(2010\)](#) have demonstrated that, compared to the basic model, the traveler incurs a larger cost when the service is scheduled, and the size of this additional cost is of course related to the service headway. For some scheduled services, it may be more relevant to consider a model where the in-vehicle travel time is known with certainty by the traveler, but the waiting time at the station is considered random. In this case, [Benezech and Coulombel \(2013\)](#) have shown that one can derive the traveler's value of mean headway and headway variability, along the lines set out in our simple model.

Trip Chains with Multiple Activities

The framework in our simple model considers a single trip, which is suitable if all journeys made by a traveler in a day are scheduled independently of each other. However, it may be the case that the arrival time at work in the morning affects the departure time from work in the afternoon, because the traveler has to work a fixed number of hours. More generally, the choices of all departure times and all activity durations for all trips and activities during the day may be interrelated. [Jenelius \(2012\)](#) has defined a trip chain scheduling model that incorporates this, and shown that it is possible, in some cases, to derive the optimal departure times using dynamic programming. For the special case with a two-trip chain between three activities, analytical values of travel time and TTV can be derived under the assumption of piecewise constant or piecewise linear marginal utilities of activity participation, which corresponds to the preferences in the step model and the slope model, respectively. The values of travel time and TTV differ between the first and the second trip, and also depend on the joint distribution of travel times on the two trips.

Time-Varying or Endogenous Travel Time Distributions

Two important assumptions in the basic scheduling model are that the travel time distribution is exogenous (the traveler takes it as given) and invariant over the period of analysis. In many real congested transport systems, however, the mean and variance of the travel time distribution vary systematically over the day, as a consequence of the departure time pattern stemming from the combined choices of all travelers. It is highly likely that travelers take the variation over time into account when choosing their departure times, which violates the invariance assumption. How well the invariance assumption approximates reality is yet unclear, and this is arguably a weak point of the model, which needs further investigation.

When it comes to measuring preferences and the value of TTV using empirical data, the exogeneity assumption might not be so important—if we are willing to assume that travelers' responses to changes in TTV do not depend on how they think other travelers react. This may be a fair assumption in many cases, such as stated preference studies. However, when it comes to predicting welfare effects of new infrastructure or policy programs, it is necessary to account for second-order effects, that is, that travelers' aggregate behavior in terms of departure time choice affects the travel time distribution. We return to this discussion in the final section.

Empirical Evidence About Preferences

Stated Preference and Revealed Preference Data

The empirical evidence about scheduling preferences under travel time uncertainty stems mainly from stated preference analyses, that is, hypothetical behavior, but there is also some evidence from observations of real behavior. Typically, the stated preference studies infer knowledge about preferences from hypothetical trade-offs between monetary costs, mean travel time, and TTV and/or departure time. In these surveys, TTV is commonly presented to the participants as a list of 2–5 possible travel times or arrival times with corresponding probabilities, or graphical representations of this. Stated preference analyses have two major benefits: First, the data are relatively cheap because surveys can be conducted over the Internet, providing large samples at low costs. Second, because the trade-offs measured in the surveys are hypothetical, it is possible to design the surveys to obtain sufficient variation in the attributes and avoid co-linearity, which is a prerequisite for statistical identification of the effects. An often mentioned disadvantage of stated preference analyses is of course that we can never be certain that respondents answer truthfully: they may have reasons for not doing so. However, in the context of scheduling preferences and TTV, it is probably just as important to consider the “observation error” stemming from respondents misinterpreting the often considerable amount of information in a choice exercise, or not making the effort to fully comprehend the consequences of the information in terms of their travel planning and activity schedule.

The revealed preference studies typically use data of route choice and experienced travel times, from which it is sometimes possible to estimate trade-offs between mean travel time and TTV, and in some cases also departure times and monetary costs. Compared to stated preference studies, the revealed preference analyses may suffer from insufficient variation in the attributes, or co-linearity of the attributes, because real-life observations of mean travel time, TTV and cost for different routes between a given origin and destination will often be highly correlated. The consequence is less precise statistical results. Until recently, data collection was also a problematic issue: The studies relied on good quality travel time data with a sufficiently fine time resolution for all relevant routes, and corresponding observation of choices and choice sets. Some studies relied on GPS-transmitters being installed in the vehicles of the participants, which was relatively expensive and usually only applied with small samples. These days, information about route choices, departure times, and travel times for very large samples of travelers has become easily available—with the potential to bring about new evidence about scheduling preferences from revealed preference studies in the near future. The issue regarding colinearity between the attributes, however, still prevails.

The Scheduling and Reduced-Form Approaches

Within the theoretical framework of our basic model, the empirical value of variability can be obtained in two different ways: One is called the scheduling approach and the other the direct or reduced-form approach. With the scheduling approach, one uses observations of trade-offs between travel time, departure time, and monetary cost. The preference parameters are estimated based on the equation for the expected utility as a function of departure time, $EU(t_d)$. There are numerous applications of the scheduling approach using the step model, both with fixed and random travel time, and the focus of these studies is usually on the estimated preference parameters. The VTTV can be derived as a function of these estimates, as set out above. In contrast to the scheduling approach, the reduced-form approach does not use information about departure times: It uses the equation for the optimal expected utility, EU^* , together with observations of trade-offs between mean travel time, TTV and monetary costs. This approach is the most common way to measure the VTTV, and usually TTV is measured by the standard deviation or variance of the travel time distribution (the mean-variance approach), or by the interquantile range. As explained, this corresponds to the reduced forms of the step model and the slope model, respectively. In theory, the scheduling and reduced-form approaches should yield similar results in terms of the VTTV, for a given underlying scheduling model, as long as we can assume travelers maximize their expected utility by choosing the optimal departure time. However, two stated preference studies by Abegaz et al. (2017) and Börjesson et al. (2012), who have compared the two types of valuations, reveal that they may be very different. Both studies find that the scheduling approach yields much lower valuations of TTV than the reduced form approach. This may be because travelers incur a disutility of variability in itself, over and above the scheduling costs, due to increased anxiety or higher planning costs, or because the underlying scheduling model is otherwise misspecified. The popular step and slope models are attractive because of their simplicity; however, it remains to be validated that they are indeed good approximations of actual behavior. And even if these simple scheduling models are good approximations of real behavior, it may well turn out that the behavior observed in stated preference trade-offs is not consistent with behavior in the real world. As mentioned earlier, this latter explanation does

seem likely, because choice tasks involving TTV are complicated to communicate without risk of misinterpretation, and complex to process in terms of the consequences for travel planning and activities. This casts some doubt on the appropriateness of using stated preference data in the context of TTV.

Application in Demand Prediction and Cost-Benefit Analysis

As mentioned earlier, application in practical demand modeling and cost-benefit analyses requires four things: (1) definition of an appropriate measure of TTV, (2) knowledge about effects of TTV on behavior in terms of departure time, mode and route choice, (3) a monetary social value of TTV, and (4) models which predict TTV for the relevant scenarios.

For cost-benefit analyses, ideally the predictions of TTV should stem from models taking both departure time choice, mode choice and route choice into account. Eventually, this may become available from the traffic models used to predict demand, but until this becomes available at a sufficiently detailed level, it is necessary to apply an ad hoc approach. Recent applications, either recently implemented or close to being implemented, involve simple TTV prediction models, that forecast the TTV based on output from traffic models, and ignore or underestimate that TTV may affect departure time patterns as well (de Jong and Bliemer, 2015).

Now, the potential errors related to using an ad hoc approach may discourage analysts and decision makers from even considering this, preferring to stick to their usual practice. To gain insight regarding the best way forward from here, we need numerical analyses of the size of the potential errors. A few theoretical or numerical illustrations are already available in the literature, but it would be useful to expand this evidence taking into account the empirical knowledge about the scheduling preferences in the population.

One such theoretical illustration stems from a bottleneck model with stochastic travel time. A bottleneck model is a highly simplified description of a transport system, usually considering a single transport corridor with a single point of congestion (the bottleneck) where travelers queue up if demand exceeds capacity. The benefit of this simple set-up is that the model can be used to derive general results analytically, whereas traffic models with large networks are much more complex and provide results that are highly context-specific and usually not easy to generalize. Using a bottleneck model where the travel time distribution is endogenous and changes over time, Xiao et al. (2017) demonstrate that ignoring the effect of TTV on departure time patterns may imply errors in project appraisal. However, the size of this error will depend on the true functional form of the scheduling preferences: If we are willing to assume scheduling preferences corresponding to the slope model or a model with a constant $h(t)$ and an exponential $w(t)$, these errors disappear altogether. In other cases, it is theoretically possible that the errors are of considerable magnitude. In other words, to make firm conclusions, we need additional empirical evidence about the scheduling preferences in the population of interest.

Introduction

Crowding in a transport context refers to the state of high volumes of passengers or pedestrians sharing limited space when walking, queuing, waiting, or traveling. Empirical evidence shows that avoiding crowding has a value for public transport users, and they often do trade this source of disutility with excess travel time or monetary payments. Thus, the value of crowding can be measured in discrete choice models of mode, route, and departure time decisions. In most cases, crowding costs are expressed in terms of a multiplier function imposed on the value of in-vehicle travel time, where the argument of the multiplier may be the density of standing passengers inside the vehicle, for example. Empirical estimates of the value of crowding are applied in various contexts. First, it is an important component of demand modeling and forecasting. Second, crowding has a role in the economic appraisal of transport investments and policies; if such interventions ease crowding, then improved travel conditions generate social benefits in the form of consumer surplus. Third, the value of crowding affects short-run supply policies targeting welfare maximization, including pricing, timetabling, fleet management, and the degree of public subsidization.

Physical and Behavioral Foundations

Crowding emerges when travelers share limited floor space and their volume reaches a level that triggers discomfort for them. In case of public transport trips, one can distinguish between crowding (1) inside vehicles, (2) during boarding and alighting, and (3) during activities before boarding and after alighting and when accessing the vehicle. From a physical perspective, passengers may experience crowding both when they move (walk) and stand still. In the former case, high pedestrian density can lead to a reduction in walking speed, and thus travel delays, due to frictions and potential conflicts between pedestrians. Such delays can be especially significant in magnitude in large stations where the access time required inside the station to get to or leave the vehicles constitutes a nonnegligible part of the total journey time. Additionally, the density of crowding inside the vehicle and on the platform or bus stop can affect dwell times, and consequently cause external travel time expansion for a wide range of passengers through the delay accumulated by the vehicle itself. In extreme cases, but in densely populated urban areas absolutely not rarely, in-vehicle crowding can lead to failed boarding, which is an even more severe source of travel time delay. All these consequences of crowding may have an additional external impact on travel utility through travel time loss and unreliability (refer to Article Valuing Travel Time Variability: Scheduling and Reduced Form Models).

In crowded situations, passengers experience a number of nuisance factors stemming from close physical proximity to fellow users. This may cause disutility through physiological stress, annoyance, and ultimately various forms of frustrations and fatigue. Major sources of discomfort include intrusion into personal space, noise, smell, increased accident risk, security concerns, and lack of access to natural light and fresh air (Haywood et al., 2017). Crowding limits the extent to which passengers can move inside the vehicle and use its amenities; for example, access to washrooms and preferred seats can be hindered by passengers blocking the interior area. Access to seating is a particularly relevant consequence of high vehicle occupancy, as standing in itself is a major source of disutility that may lead to physical tiredness and pain, even if a passenger is not surrounded by other standees at all. Similarly, the difficulty in accessing the doors is a major concern for travelers in crowding, as failure to reach the doors at the desired destination station can lead to various unexpected travel costs, including a detour.

It is important to note that, in contrast to other user cost components in transport, the micro-foundations of crowding disutility have not been established in the literature so far. The value of travel time loss and the disutility of monetary payments, for example, can both be derived from time and monetary budget constraints of the utility maximizing individual. In the former case, travel time

as a resource may be costly because it impacts the amount of time available for leisure or paid work, and this disutility can be quantified separately from the inconvenience of in-vehicle crowding. By contrast, there are no known models of such thing as a *discomfort budget*, from which people's aversion to crowding and the shadow price of relieving could be derived in a theoretically sound manner. Intuition suggests that spending time in crowding may have a negative impact through fatigue on people's productivity at work as well as their need for leisure time and recovery, but the mathematical formulation of this dependency and its empirical validation is an outstanding task on the research agenda.

Measuring the User Cost of Crowding

Crowding causes disutility for travelers, and measuring the magnitude of annoyance is essential to predict user behavior with high precision and develop efficient supply-side policies to mitigate the inconvenience. Crowding disutility cannot be modeled independently of other travel attributes, such as the costs of accessing public transport, and spending time while waiting or traveling inside the vehicle, because we can hardly observe situations in which crowding varies but the remaining travel attributes are constant. From both a chronological and methodological point of view, the measurement of the value of crowding had been predominantly part of value-of-time estimation experiments (refer to Article Estimating the Value of Time).

The majority of the empirical literature estimates the cost of crowding by modeling and calibrating observed or stated discrete travel decisions, where passengers trade crowding inconvenience with monetary expenses and/or travel time loss (Li and Hensher, 2011; Wardman and Whelan, 2011). Such trade-offs happen, for example, when one selects the departure time, mode, and route before a trip. The severity of crowding, just like other travel attributes, varies by time, space, and direction in a large public transport network. Thus, the choice of mode, route, and departure time implies a comparison of relative crowding costs between available alternatives. Random utility discrete choice modeling offers a suitable method to calibrate a utility function of crowding and other discomfort factors that best explains the observed choices, conditional on the assumption that passengers select the alternative providing the highest level of utility. On this basis, the rate of substitution between crowding disutility and other nuisance factors can be revealed. When the comparison is made with monetary costs, in particular, the rate of substitution measures the marginal willingness to pay to avoid crowding.

Modeling Travel Disutility

The functional form of the underlying utility function, that is, the way how crowding is assumed to be related to other travel attributes, is a critical challenge of the estimation process. In the simplest case, a suitable measure of crowding can be an additively separable component, where its coefficient is simply the marginal utility of crowding. This approach implies, however, that crowding discomfort is completely independent of other travel attributes, including the time spent inside the vehicle. This assumption is arguably rather unrealistic, and thus the resulting estimate could not be applied in other choice situations unless travel time is constant. It is more common in the literature to assume that crowding affects disutility as a multiplier of the value of time. From the viewpoint of the specification of utility, this implies that the function needs to include a travel time attribute, and an interaction term of travel time and the measure of crowding. This is where the literature stands right now.

What do we mean by a suitable measure of crowding? The challenge here is to define quantitative or qualitative metrics of crowding that create a good association between what enters the model and what the observed passengers perceive. In early contributions to the crowding literature, the occupancy rate of seats was used for this purpose, allowing the metric to go above 100%, thus expressing the number of standees relative to seating capacity. This approach has the obvious limitation that the metric changes if we add or remove seats, keeping the total number of people on board constant. One may also express vehicle occupancy in percentage terms, assuming a theoretical capacity, including both standing and seated passengers. It is a usual industrial practice to set this theoretical threshold to four standing passengers per square meter. However, the resulting estimates still cannot be applied for vehicles with varying seat-to-standing-room ratios, as densely seated vehicles reach the theoretical capacity much earlier, while, in fact, more passengers travel more comfortably in such vehicles. To overcome the difficulties associated with interior layout, it is rational to distinguish the disutility of standing from discomfort stemming from the density of passengers. Recent contributions in the literature treat the probability of standing and the density of standing passengers as separate factors of the value of time multiplier, where standing density is normally expressed in terms of the average number of standees sharing a unit of floor area (Wardman and Whelan, 2011).

Another critical question of model specification is whether disutility is a linear function of the density of crowding, or more complicated functional forms should be applied to represent passenger experience adequately. Convex functional forms may be appealing intuitively, in line with the usual cost functions applied for modeling road congestion. However, the existing literature has not found empirical evidence of a nonlinear relationship (Wardman and Whelan, 2011), meaning that linear specifications achieve better model fit and coefficient significance in the observed range of crowding levels. Note that we cannot assume on this basis that crowding costs increase linearly without any upper bound on possible equilibrium occupancy rates. Very dense crowding leads to failed boarding, inducing considerable delays for passengers. The researcher may treat the time cost of denied boarding as part of the expected waiting time, but eventually, the occupancy rate function of the aggregate user cost must at some point become very steep, if one intends to exclude the possibility of unrealistically high in-vehicle crowding levels as a model outcome.

The issue of nonlinearity arises in case of the interaction with travel time as well. Traveling in crowding causes fatigue, especially while standing, and tired passengers may be more sensitive to the disutility of high vehicle occupancy. This implies that the crowding multiplier on the value of a unit of time should increase with the travel time itself. In the empirical literature there is a tendency toward higher crowding cost estimates for medium- and long-distance services compared to shorter urban public transport trips, but, to the best of our knowledge, there is no published study in which an endogenous, travel time dependent crowding multiplier function is estimated explicitly. This opens up room for new empirical contributions.

Finally, let us note that despite the mainstream literature tends to focus on very high vehicle occupancy rates in the context of crowding costs, the marginal trip may cause disutility under more relaxed demand conditions as well. [Wardman and Murphy \(2015\)](#) show that passengers may have strong preferences for using certain seats in public transport vehicles, for example, the ones facing forward or located close to the window. Users sometimes even decide to stand instead of using an unattractive seat. Thus, if a passenger's most preferred seat is already occupied by someone else, the marginal cost of that fellow passenger's trip can be relatively high, despite the negligible occupancy rate and the fact that no passenger is forced to stand.

Data: Declared and Revealed Preferences

To estimate the value of crowding successfully, the underlying data should comply with four essential criteria: it has to provide information on (1) what alternatives a decision-maker considered before selection, (2) which one was eventually chosen, (3) data should be available on expected travel conditions, including all attribute levels for each alternative, and (4) there must be sufficient variation between alternatives in crowding conditions as well as other attributes to make coefficient estimation possible. Criteria 1–3 depend on the data source and data quality, while the last one depends on the choice situation itself. In the upcoming discussion we review the most often cited pros and cons of stated and revealed preference (SP and RP) methods.

Survey-based data collection offers a number of advantages compared to recording RPs. As the choice situation is artificial in a survey, the researcher can be sure about what alternatives the decision-maker considers, and expectations about various attribute levels are also unambiguous. Moreover, with appropriate survey design methods, sufficient variation in attribute levels can also be guaranteed. On the other hand, the downsides of these idealized experimental conditions are numerous: responses may not be fully in line with how passengers behave in reality; only subsamples of the entire population of travelers can be involved in the experiment; and data collection is generally more expensive than using existing automated datasets.

Representing crowding in an easily perceivable manner for respondents is one of the main challenges of the SP approach. The literature suggests that users cannot associate crowding densities expressed in terms of the number of passengers per square meter with their personal experience, so some form of verbal or diagrammatic representation is required to explain or visualize occupancy rates. Plan view images, photos, and stylized axonometric drawings are the most usual forms of representation. Recent empirical results show that in case of crowding cost estimation, the actual form of visual representation has no severe influence on the estimated coefficients. Declared preference studies are in a majority among crowding cost estimation experiments. It is indeed a huge benefit of the stated preference method that *expectation formation* is not an issue in their case. That is, in a survey the researcher has perfect control over the alternatives as well as the attribute levels considered by respondents.

Choice models can be calibrated using data on the observed behavior of real passengers as well. In an RP setting it is not easily evident what alternatives were available for the user before selecting a route or mode, for instance. It is even less obvious what attribute levels she or he associates with the available alternatives. Furthermore, the actual crowding level a passenger experiences on a trip, which can be recovered from smart card data, for example, is not necessarily in line with her prior expectation. The lack of uncertainty seems like a comparative advantage of the SP approach, but in fact passengers rarely face travel decisions in which they know deterministically the exact travel conditions a priori. The cost of uncertainty can be an important component of the discomfort associated with crowding in public transport.

Occupancy rates may vary during a single journey as well. It is often the case that passengers have to stand at the beginning of a trip, but later on the chance of getting a seat increases to same extent. In the SP framework the representation of varying travel conditions becomes too complicated. Intuition suggests that the probabilistic treatment of standing and traveling in crowding is more realistic, simply because this is the only way public transport users consider crowding when selecting the mode and route of traveling. [Hörcher et al. \(2017\)](#) illustrate that the combination of smart card and vehicle movement data is a suitable and attractive source of information to perform the three main steps of crowding cost estimation: (1) recover the pattern of occupancy rates of vehicles in a network where multiple potential routes exist for at least a subset of users, (2) derive the expectation of passengers departing at a given point in time on the level of crowding along potential routes considered, and (3) infer the actual route chosen. In the currently available literature, expectation formation in step (2) is limited to the assumption that regular commuters are familiar with the mean occupancy rate of network segments used in their respective time of departure. However, future contributions may extend this approach, and model expectations, using the past experience of each regular passenger, encapsulated in a time series of smart card data. Note that even if expectations are estimated correctly, it is possible in an RP setting that crowding on alternative routes does not differ sufficiently to get reliable estimates.

The magnitude of uncertainty regarding the crowding experience prior to a trip may have an adverse effect on travel utility, in a fashion similar to travel time variability (refer to Article Valuing Travel Time Variability: Scheduling and Reduced Form Models). The micro-foundations of crowding variability, however, are less straightforward than the link between the likelihood of late arrivals and schedule delay costs.

The majority of published crowding cost estimation studies use a representative consumer approach assuming homogeneous attitude toward crowding, despite the fact that the methodological toolbox of measuring heterogeneous preferences has been available for more than two decades. A potential reason is that the measurement of heterogeneity is not crucially necessary for some of the applications, such as the cost–benefit analysis of crowding reduction projects. Recent empirical research efforts by [Tirachini et al. \(2017\)](#), built on mixed logit and latent class discrete choice models, show that heterogeneity does exist, and age, gender, and income are among the influential factors correlated with crowding avoidance.

Typical Empirical Estimates

In this short review, let us concentrate on existing estimates of the occupancy rate dependent travel time multiplier, where the rate is expressed in terms of the density of standing passengers. As a rule of thumb, the penalty for standing, measured as a value of time multiplier, is normally between 1.1 and 1.6. Specifically, this value is found to be 1.54 in major Swedish cities, 1.43 in suburban London, 1.29 in Paris, 1.26 in Hong Kong, and 1.1 in Santiago, Chile. In very dense crowding, the standing multiplier goes up to 2.21 around London, 2.13 in Swedish cities, around 2 in both Hong Kong and Santiago, and 1.6 in Paris. Empirical evidence shows that seated passengers are also negatively affected by the density of standees; their value of time multiplier peaks at 1.71 in Hong Kong, 1.67 in Santiago, 1.54 on suburban lines around London, 1.50 in Sweden, and 1.41 in Paris (for a more detailed comparison of the empirical results above, see [Tirachini et al., 2017](#)). In relation to systematic differences between the estimates of SP and RP studies, some authors state that SP methods tend to overestimate the value of crowding, especially in case of standing multipliers. However, this is not a consensual finding, nor one supported by a quantitative meta-analysis, primarily because the number of RP experiments available in the literature is still very limited.

In terms of heterogeneity in crowding valuations, for the specific case of Santiago, Chile, [Tirachini et al. \(2017\)](#) report that younger, high-income males are less sensitive to crowding discomfort, while females, the elderly, and, interestingly, low-income travelers form the other extreme of the distribution. At least in this particular city, the median value of crowding, derived in a mixed logit setting with lognormal distribution, happens to be very similar to the point estimate of a simple multinomial logit (MNL) model. This implies that the more simple MNL approach gives sufficiently reliable estimates when the goal of the analysis is to model aggregate behavior. On the other hand, heterogeneity can be important in pricing models, as we often see in the second-best infrastructure pricing literature (refer to Article Second-Best Congestion Pricing).

Crowding in Models of Optimal Transport Supply

For a given public transport capacity, the disutility experienced by the average user increases with demand. This implies that crowding has to be considered as a consumption externality. Empirical evidence suggests that the external crowding cost of peak-hour trips is a nonnegligible part of its marginal social cost. That is, unless the value of this externality appears in the price of using a public transport service, passengers tend to overconsume it, thus generating potentially significant deadweight loss for society ([Tirachini et al., 2013](#); [De Palma et al., 2015](#)).

Crowding breaks the paradigm that public transport is an uncongestible substitute of car use. That is, policy-makers have to be careful when underpricing public transport with the aim of tackling car congestion, because suboptimal fares may lead to overconsumption and welfare losses. Until the wider dissemination of crowding cost estimation techniques reviewed in the previous section, the literature of optimal public transport supply was dominated by models built on waiting time costs and the Mohring effect (refer to Article The Mohring Effect). Adding crowding costs to a public transport model is expected to lead to higher fares and lower subsidies in optimum. One can reach this intuitive conclusion from the Mohring–Harwitz cost recovery theorem as well. The theorem states that under certain assumptions, including perfectly divisible capacity, the optimal degree of self-financing equals the elasticity of operational costs with respect to output (which is one in case of neutral scale economies) plus the degree of homogeneity of the user cost function. If the user cost function contains waiting time only, then its degree of homogeneity is -1 , so that the optimal cost recovery ratio becomes zero. By contrast, if user costs are dominated by the occupancy rate dependent crowding inconvenience, then the user cost function's degree of homogeneity turns into zero, and optimal pricing results in perfect self-financing ([Hörcher and Graham, 2018](#)). Since crowding is very likely to have a bigger impact on travel utility than waiting time in high-frequency public transport services, the theorem implies that, *ceteris paribus*, the cost of capacity provision should be recovered by fare revenues to a greater extent than in low-density public transport. At the same time, density economies in operational costs (refer to Article Operation Costs for Public Transport), substitution with underpriced road congestion (refer to Article Second-Best Congestion Pricing), and positive agglomeration economies (refer to Article Wider Economic Impacts of Transport Investments) may still provide second-best motivations for subsidization, even in the case of a heavily crowded service.

Are there effective strategies in capacity provision that eliminate crowding entirely? Even if such strategies exist, they are likely to be wasteful and very inefficient from a social welfare point of view. The reason why crowding is inevitable to some extent in a public transport network is that travel demand is unbalanced in spatial, temporal, and directional terms as well ([Hörcher and Graham, 2018](#)). For technological reasons, capacity (i.e., frequency and vehicle size) cannot be varied as quickly as demand fluctuates. Therefore, a given second-best capacity often has to be in service under various demand conditions. This leads to suboptimally low occupancy rates in certain time periods and network sections, and inevitable crowding in the peak. The literature of multi-period public transport supply suggests that the optimal size of vehicles increases with the degree of demand imbalances

at the expense of frequency, and the underlying reason is crowding: if demand is concentrated in a small subset of markets served by fixed capacity, then the relevance of crowding discomfort once again increases relative to waiting, even if aggregate demand remains constant.

Due to the inflexibility of capacity, differentiated pricing remains the last resort to mitigate the crowding-related consequences of demand fluctuations. In the past, the implementation of either temporally or spatially differentiated pricing was complicated from a technological point of view, especially compared to the convenience and simplicity of flat fares and travel passes. However, the advent of the digital age and new mobile payment technologies enable public transport operators to move their tariff systems closer to marginal crowding cost pricing. With differentiated pricing, crowding can be moderated in the most densely used network sections, while capacity utilization can be improved in off-peak periods and line sections.

Concluding Remarks

Crowding research is an emerging subject in the field of transport economics. Its relevance is undeniable in large metropolitan areas where mass public transport is a primary means of mobility due to the scarcity of space, as well as in economies where car ownership is not affordable for a significant part of society. The core policy messages of transport economics apply for public transport as well. We should not expect that we can build our way out of crowding by simply adding more capacity; indeed, induced demand is even more often neglected in a public transport context than in the case of road expansion. Nevertheless, capacity expansion does have the potential to improve social welfare, even if crowding reemerges due to induced demand. Crowding cannot be eliminated completely with differentiated marginal cost pricing either, but it provides the right incentive for passengers to perform trips that generate more benefits than costs for society as a whole.

Introduction

Nowadays, in developed countries, urban passenger transport demand is dominated by daily trips between home and workplace, especially during the morning and evening peaks. The evolution of transport demand is thus mainly governed by the evolution of the location of residential units and job location, that is, by urban dynamics. We discuss below the interactions between transport and urban development, sometimes referred to, in the literature, as the “chicken and egg” problem (see, e.g., [Rodrigue, 2020](#), chapter 8.2).

Transit investments shape urban dynamics, but such investments also react to increased demand for transit induced by urban dynamics. The process of urbanization and development of public transportation goes hand to hand. However, the dynamics may vary over time and over space. Sometimes, population and job relocate before the construction of new transit infrastructures, partly because households, firms, or stakeholders want to buy property before real estate prices increase. Such anticipations usually occur when a large investment in public transit infrastructure (such as Crossrail or the Grand Paris Express) is planned. See [Picard and de Palma \(2019\)](#) for details. In other cases, the relocation of residential units or the conversion of single-family residential units to multifamily housing or to mixed development units, and more generally densification occurs after the construction of mass transit. One of the reasons is the uncertainty concerning the time to complete the transit investment and the uncertainty related to a snow bowl effect generated by urbanization, which involves a complex pattern of interactions within and between sectors.

The urban development process is complex and requires detailed econometric analysis to be quantified (see [Antoniou and Picard, 2015a](#) for the econometric methods relevant for measuring each relation in this complex system). For example, the price of land is not monotonic with respect to the distance to a railway station, to a bus station or to a metro station. This is because public transit generates both positive and negative externalities. Positive externalities are related to the positive effect of transit on accessibility. Improved accessibility in turn changes the social mix and moves jobs within and between regions, and generates agglomerations effects. Negative externalities include noise, pollution, and possibly higher crime rates. Such combination of positive and negative effects may give rise to multiple equilibria, as discussed below. Econometric models can be used to measure the mutual influences between transit investments and urban dynamics. The relationships between transit and land use is involved, and it also depends on the specific legislations in urban areas, such as zoning, reserved areas, green areas and the like.

Based on standard economic principles, all other things being equal, the local demand for dwellings or offices decreases with local real estate prices, whereas local building supply increases with local real estate prices. Local real estate prices in turn increase with local demand for dwellings or offices, and decreases with local building supply, all other things being equal. From the mathematical point of view, this means the long-term real estate prices, population and job locations, and transport demand are the solution of a fixed-point problem associated to a nonlinear system of equations. Standard tools based on [Kakutani \(1941\)](#) fixed point theory guarantee existence of a solution for systems of nonlinear equations, under quite realistic assumptions. Other tools (based e.g., on contracting mapping or on diagonal dominance like in [Ginsburgh et al., 1985](#)) guarantee uniqueness under far more restrictive and often unrealistic assumptions. For example, uniqueness is not guaranteed when positive externalities are high enough, or if population is characterized by heterogeneous preferences or firms are heterogeneous. This leaves room for policy analysis in order to uncover instruments to help the selection of the “best” equilibrium solution in terms of efficiency and sustainability.

Dynamic models offer a different view, and provide a path to stationary solution(s). In the case of multiple equilibria, dynamic models offer powerful tools to analyze how public policies may contribute to the selection of the preferred equilibrium solution. The way agents acquire, transmit, and process information may induce a time dependency of the final solution. When positive network externalities are strong enough (with respect to negative externalities), multiple solutions may arise. As a result, two forces are opposed, and the modeling of the dynamic path allows selecting the specific solution. For example, according to [Brueckner et al. \(1999\)](#), the location of the most preferred local amenities explains why the equilibrium selected concentrates the rich population in central Paris, but the poor population in downtown Detroit.

The question of which comes first, the chicken or the egg, is not only a philosophical one, it is also of primary relevance for policy evaluation. In the context of demand analysis, the chicken-and-egg problem refers to simultaneity, endogeneity, and causality. There is a simultaneity problem because the drivers of transport demand such as local economic activity, performance or growth also influence transport supply, and because transport demand depends on transport supply, and vice versa. Such interdependencies raise endogeneity problems in the measurement of transport demand functions, in particular in the computation of various elasticities.

In such a context, the relationship observed empirically between transport demand and transport supply reflects both the elasticity of transport demand to transport supply, the elasticity of transport supply to transport demand and the effect of confounding factors (drivers of transport demand) affecting both transport demand and supply.

Such problems are not specific to the context of transport, and they have given rise to a very rich literature in macroeconometrics, in relation to various economic theories. The most popular methodology to go from correlation to causality measurement relies on the dynamics of interactions, with the famous notion of [Granger \(1969\)](#) causality. The idea is to rely on the timing of variables evolution. Variable A causes variable B in the Granger sense if a change in A tends to be followed, one or a few periods later, by a change in B. However, when agents anticipate consistently, the consequence may happen before its cause. For example, when a couple is expecting a baby, they usually decide to move to a larger dwelling before the baby is born. The birth is the cause of moving, but it is generally observed after its consequence (the move).

This article is mainly focused on Western Europe, and restricted to urban passenger transport demand (expressed by individuals living in households), which excludes freight, airplanes, and high-speed trains. The next section reviews the drivers (determinants, causes) of transport demand, and their trends. Most of those determinants are also affected by transport demand, giving rise to a chicken-and-egg problem. The basic four-step model provides an illustration of interdependent decisions leading to a chicken-and-egg problem and stresses the role of anticipations. After reviewing the different sources of endogeneity in a general setup, we analyze the chicken-and-egg problem in the light of Interactions Land Use and Transport. We finally argue that taking into account gender differences in transport demand, and the interactions between individuals in the same household transforms the chicken-and-egg problem into a chicken, egg, hen, and cock problem.

Trends and Drivers of Transport Demand

[Sessa and Enei \(2009\)](#) provide a review of transport demand trends and drivers from 1995 to 2007. They stress that passenger transport demand (expressed in passenger kilometers travelled) in the 27 EU countries has decreased by 7.7% for maritime transportation, and increased by 21.4% for cars, 24.8% for powered-2-wheel, 6.9% for bus and coach, 12.7% for railway, 20.1% for tram and metro, and 70.4% for air. All modes together, the increase is 22.3% for this period, which represents an average of 1.7% per year. The car mode share, 72%, is stable over the period. The long-distance (over 100 km) trips account for 2.5% of the number of trips and 53% person kilometers.

These trends were significantly affected during the last decade by the emergence of new transport services and systems such as Mobility on Demand, Mobility as a Service, vehicle-sharing, ridesharing, or autonomous vehicles. This emergence was mainly driven by rapidly developing mobile information and communication technologies. See [Antonioni et al. \(2019\)](#) for details.

More recently, the COVID-19 pandemic has dramatically reduced transport demand, especially for air and public transport, while dramatically increasing the shares of walking, cycling and other new energy-friendly modes. According to [Sung and Monschauer \(2020\)](#), the Covid-19 crisis has changed already people's transport behaviors in dramatic ways, with large reductions in aviation and public transport use and significant growth in cycling uptake. They argue that "Evidence from previous crises shows that in the immediate aftermath of crisis events, transport behaviors will change, as people reassess the costs and benefits of different transport modes." [Abu-Rayash and Dincer \(2020\)](#) seem less optimistic about the long-term effects on the environment, possibly because their study covers a slightly longer period after the end of the lockdown policy. Indeed, their mobility index significantly increased again in May or June in Moscow, Paris, Brussels, Singapore, or Hong Kong, for example. Although it is too early to assess accurately the long-term effects of the Covid-19 pandemic, the other long-term trends can be better assessed by analyzing the trends in the usual transport demand drivers. Changing mobility behavior may influence location patterns, which may in turn call for new developments of transport infrastructure, another chicken-and-egg illustration.

Starting with **demographic drivers**, there is a clear consensus that transport demand depends on age, and that population is ageing in most of developed countries. At a given period and in a given country or region, travel demand significantly depends on age, reflecting a mix of the effect of age and of generation. On the one hand, above a certain age, a given person tends to travel less, and the car mode share decreases with age; on the other hand, as argued by [Sessa and Enei \(2009\)](#), "it can be expected that the future old people will travel more than previous generations of older people did." Moreover, the car mode share will probably be larger within the generation which will be over 60 in 20 years than within the generation currently over 60. In addition, older people tend to live farther away from the CBD than younger generations, which typically increases their need for mobility, at least until they retire. Finally, older people are richer on average, and thus have a larger demand for medium and long distance leisure trips. All in all, in the long run, population ageing will probably induce more inter-urban trips, by train, car, and air, and more urban trips by public transport and car.

International migration is the second demographic driver of transport demand mentioned by [Sessa and Enei \(2009\)](#), with nearly 100 million people expected to migrate from developing countries (mainly from Asia) to developed countries (mainly in North America, Western Europe, and Australia) between 2005 and 2050. Migration will largely offset the natural decrease in population (more deaths than births) in developed countries, whereas it will represent less than 5% of population growth in

developing countries. If migration flows remain younger, with higher fertility than natives, and mainly directed toward the outskirts of agglomerations, they will result in more short distance trips in urban areas by car and public transport. Moreover, the first generations of immigrants are expected to become richer, which will further increase future transport demand by individual means (cars, motorbikes, etc). The (chicken-and-egg) question is who comes first, international migration or urbanization?

Urbanization (from about 1/5 of European population in 2015 to about 4/5 in 2030) is expected to be associated with increased urban sprawl, that is a relative shift in the location of housing and activities toward the peripheries of the urban agglomeration, in a context where land resources are already relatively scarce. Achieving a sustainable balance between competing land uses will thus become more and more a key issue for development policies in Western Europe. Urban sprawl is usually associated with an increasing dependence on the automobile, either as the single mode for commuting, affairs and leisure trips, or in association with public transport for daily commuting trips between dwellings typically located in the suburbs and jobs typically located closer to the CBD. All in all, urbanization should result in an increase of local and short distance trips using collective transport and short-medium distance trips by car. The (chicken-and-egg) question is who comes first, urbanization, urban sprawl, or commuting decisions?

The first **economic driver** of transport demand is **gasoline price**, which depends both on international markets and on national taxation policy. Gasoline is heavily taxed in most European countries (about 70%), whereas tax represents only 21% of gasoline price in USA, 38% in Canada, 48% in Australia and New Zealand, and 53% in Japan. In international comparisons, the negative effect of gasoline price on transport demand by car (price elasticity) is difficult to estimate because of the confounding effect induced by population density and the availability of alternatives to car. [Sessa and Enei \(2009\)](#) argue that, when energy prices become very high, they become the main barrier to global trade. The possible answers to a fuel price increase are: switch to a more fuel-efficient or electric vehicle; consolidate or link trips; carpool and other modes (walking, biking) shifts, relocation of residence or activity, and (more and more in reaction to COVID-19 pandemic) teleworking. Polycentric cities offer opportunities for reducing commuting distances because they offer more possibilities to make jobs and dwellings closer, and to reduce congestion on the transport network.

The second economic driver of transport demand mentioned by [Sessa and Enei \(2009\)](#) is **GDP growth**. They report an elasticity of passenger transport to GDP of 0.9 in EU for the period 1990–2005, with a projected decrease to 0.65 for the period 2005–2030. This corresponds to a 1.4% yearly increase in passenger transport demand between 2005 and 2030 and suggests a decoupling between GDP growth and passenger transport demand. It is too early to find updated figures showing how the elasticity and the passenger transport demand reacted and will react further to the huge decrease in GDP during the pandemic. The (chicken-and-egg) question is whether insufficient transport supply slows down GDP growth, or faster GDP growth increases transport demand?

Turning to the **technical drivers** of transport demand, [Sessa and Enei \(2009\)](#) argue that, if one assumes reducing but stable economic growth, and sustained international trade and urbanization, then the technological opportunities offered by the development of **Information and Communication Technologies** may influence transport demand in the following directions. A reduction in travel frequency, but perhaps longer distance travel (individuals move further from work, due the globalization trends); substitution of work travel with other travel (with time saved by not travelling to work), due to widespread diffusion of flexible and remote working technologies. ICT may induce a modal shift toward public transport, due to new technologies (Integrated public transport planning information, e.g., real time information on bus schedules) and E-ticketing. Paradoxically, Real-time route guidance and hazard warning will obviously help saving in congestion and travel time, but may also increase distances travelled. The (chicken-and-egg) question is whether ICT technological developments were induced by the pressure of the demand to improve the efficiency of transport systems, or ICT innovations shaped transport demand?

The aim of **new transport infrastructures** is not limited to serving already existing or anticipated business-as-usual transport demand resulting from urban development. In the case of transformational projects such as the Grand Paris Express, they also aim at enhancing urban development and economic growth, by attracting the most productive workers and firms in the region. Such densification of high-productivity economic activity induces agglomeration effects, as detailed in the section analyzing Interactions between transport and urban development. This places the chicken-and-egg problem at the core of the evaluation of transport infrastructure investments.

Last but not least, **lifestyle changes** are important drivers of the changes in transport demand. For example, in most European countries, owning a car starts not to be seen much as a status symbol (at least among parts of the younger generation) and the only provider of “mobility freedom” in the younger generations. A new sustainable mobility freedom concept is emerging in the urban environment, with a mode switch toward active travel (walking and cycling), and from car (driving alone) toward carpooling and public transport. The mode switch from car to public transport was, however, more or less stopped by the COVID-19 pandemic. The chicken-and-egg problem in this context is whether lifestyle changes in residential location and transport demand are made possible by economic growth and availability of cleaner and more environment-friendly transport modes, or whether new ecological and sustainability concerns imposed enough pressure to promote technical changes and enhance a more sustainable urban development.

The Basic Four-Step Model

Several modeling approaches have been used in the literature for studying travel demand. In the light of the chicken-and-egg problem, these approaches differ with respect to their inclusiveness of choice dimensions (do these models consider other choices made simultaneously, or interacting, with transport choices) and their forward and backward consistency, as discussed below.

Urban transportation planners have traditionally used the so-called classical model, which incorporates the following interdependent four choices. (1) Trip generation (choice of number of trips by purpose, origin, and destination of each trip) produces the aggregate number of trips in the system by origin, by destination, and by purpose. Since most trips at rush hours are commuting trips, trip generation depends on the location of households and jobs. (2) Trip distribution links origins and destinations, that is produces O-D matrices of number of trips by purpose, by O-D pair. This step typically relies on gravity or an entropy model. (3) Mode choice is typically described by binary or multinomial logit model, and (4) Assignment is specific to the mode used. Assignment usually relies on minimum distance, or minimum general cost.

The classical model has been applied with some success to analyze major infrastructure investments. However, it is not well suited for evaluating policies such as road pricing that are designed to modify travel behavior in a substantial and/or comprehensive way. The first reason is related to the endogeneity of attributes in the different steps of the model, as explained in the endogeneity section below. This chicken-and-egg problem can be solved by using adequate econometric techniques such as instrumentation, fixed effect modeling or other difference in difference techniques to correct for the endogeneity of attributes. Such corrections are crucial because policy evaluation requires a precise and unbiased estimation of the determinants of travel demand. In the case of stated preferences surveys, [de Palma and Picard \(2005\)](#) argue that the best way to correct for the endogeneity of attributes is to introduce enough randomness when selecting the value of each (endogenous) attribute.

The second reason is related to the interdependence of the individual choices leading to the four-step model. As noticed by [de Palma et al. \(2005\)](#), “it would simplify matters greatly if travel decisions could be modeled as if they were made sequentially, rather than simultaneously, since the number of choice combinations to consider would be reduced from the product of the number of choices at each level to the sum.” A sequential approach, to be valid, should ensure the consistency of choices in both “forward” and “backward” directions. Consistency in the forward direction matters because upper-level choices determine lower levels opportunities. For example, before car sharing was available, and neglecting car rental, the car alone mode was not available to those who decided not to own a car. Consistency in the backward direction also matters because preferences for options available at a lower level affect the relevance choices made at upper levels. For example, if commuting by car becomes more interesting because congestion is alleviated, this increases the expected utility of buying a car. See the anticipation and nested models below for more details.

Car use and car ownership are thus closely related. The chicken-and-egg problem arises because forward and backward consistency implies that they influence each other. Is it the case that you do not drive by car because you do not own a car, or you decided not to buy a car because you anticipated you would not use it much? The answer to these questions is typically given by the Nested Logit model, which ensures the consistency of choices in both “forward” and “backward” directions. The four-step model can be interpreted as the result of individual nested decisions amenable to a Nested Logit model. The top of the individual decision tree corresponds to long-term decisions such as location and vehicle, ownership. The bottom of individual decision tree corresponds to short run parking location. The three choices considered in the road-pricing studies typically correspond to medium run decisions such as travel mode, departure time, and route.

Sources of Endogeneity: What Generates the Chicken-and-Egg Problem?

Endogeneity has attracted the attention of economists and econometricians for decades, since it represents a major stake for policy evaluation. For an easy-to-read introduction on this topic, the reader is referred to [Greene \(2017\)](#). We detail below the main sources of endogeneity in the estimation of transport demand. In the transport context, the different causes of endogeneity can be illustrated by the choice of lane experiment analyzed by [Lam and Small \(2001\)](#). See [de Palma et al. \(2005\)](#) for an explanation of their method and results to a noneconometrician audience.

Common Determinants and Heterogeneity

Departure time was traditionally treated as given in the lane-choice model. Such a specification is misleading because departure time affects the explanatory variables (expected travel time, variability in travel time, and toll) on both lanes. Since unobserved factors may influence both departure time choice and lane choice, the explanatory variables and the error terms in the lane-choice equation may be correlated, which invalidates the standard regression model. For example, if your (well-paid) job starts at a popular time and requires punctuality, you will prefer both to travel at the height of the rush hour and to use the toll lanes to reduce the chance of delay. In this case, the unobserved factor, the type of job, induces a positive correlation between departure time and use of the toll lanes. This typically leads to overestimate the coefficients of the explanatory variables, and thus the Value of Time and the Value of Reliability.

The best way to solve this endogeneity, or chicken-and-egg problem is to include all the common determinants (here, the type of job) in the model estimated, so that their effect is not relegated to the error term.

Reversed Causality and Simultaneous Decisions

A typical example of reversed causality is when demand is induced by supply, and at the same time, supply is induced by demand, which is the case when transport policies aim at serving the demand. [de Palma et al. \(2005\)](#) stress that “Until the 1980s the UK approach to combat traffic congestion was to forecast demand, and then to add enough road capacity to accommodate it.” Such

“predict and provide” strategy is naturally undermined by the tendency of new roads to fill up with additional traffic demand induced by supply. In the short-medium run, this additional demand is mainly diverted from other routes, other modes, or other times of day. In the longer run, it mainly corresponds to new trips induced by additional activities (nonnecessary activities become interesting when congestion is reduced) or household and job relocation (households can locate farther away from the CBD if they anticipate less congestion, even though it finally turns out to be a bad decision when congestion increases again after a few years).

Interactions Between Transport and Urban Development

From the point of view of public policy, the question is not which comes first, but rather which one is the most sensitive to public policies, and more broadly to what extent is optimal public policy design affected by the mutual influences between transport, land use, and economic growth.

Land Use and Transport Interaction models aim at analyzing, measuring and predicting long term interactions between transport and land use, households and firms location, real estate markets, labor markets, economic activity and more generally urban development. They have received increased attention both in research and in practice over the last decades. Researchers and decision makers highlight the ability of these integrated models to examine the combined effects of land use and transport policies, to study the endogeneity of urban development and of travel patterns, as well as to analyze and quantify the effects of transport network expansion and policies in transport, dwellings, employment, or environment. They can be used to answer a large variety of important questions such as the following. What would be the optimal timing for building the different segments of the network over the years to come? What is the list and order of magnitude of the wider economic benefits? How many jobs will be created or attracted in the region in reaction to transport infrastructure development, in the short, medium, and long run? When and where will the different economic agents (residents and businesses) relocate after transport network extensions? This last question is important since it will help local authorities to cope with the demand for housing (especially regarding collective dwellings) and for offices. How will the traffic demand evolve, both in the existing and new public transport network, and on roads?

LUTI models differ in the way they model agent behavior and market (dis)equilibrium, in the degree of agent heterogeneity they can handle, in their level of geographic aggregation level and Geographical Unit of Analysis, in the complexity of their data requirements, and in the type of policies they can reasonably simulate. Different agents make different interrelated decisions, which systematically raise chicken-and-egg problems. Individuals/households choose tenure status (owner vs renter), dwelling type (single vs collective dwelling unit), residential location, activity, job location, job type and activity sector, and daily mobility (mode choice). Firms choose establishment location, number of jobs, wages, quality and quantity of goods produced, and prices. Public authorities (State, Region, Agglomeration, City) make choices related to Transport infrastructures, building permits, urban development policy, social dwelling and fiscal competition, using different tools (public investments, contribution to PPP, regulation). Other private decision makers and stake holders (transport companies, promoters, large firms, . . .) decide private investments, contribution to PPP, and lobbying. Real estate and labor market model the interactions between supply and demand, and the role of real estate prices and wages in reducing (possibly to zero) the gap between supply and demand.

LUTI models can be classified in two main categories with respect to their focus either on the dynamics of evolution of final point reached, their assumption of (general or partial) equilibrium versus disequilibrium, and with respect to their implications in terms of unicity versus multiplicity of equilibria.

The RELU-TRANS General Equilibrium model developed by [Anas and Liu \(2007\)](#) is representative of the first category. It assumes general equilibrium and is only interested in the final point reached by the system at equilibrium. Since its complexity is a convex function of the degree of agent heterogeneity, it is usually limited to 2–3 income classes, 2–3 classes of household composition, 3–5 activity sectors, and 2–3 qualification levels. It usually models either individuals or households, or implicitly assumes that each household is made of one representative member. It requires a rather limited amount of (aggregate) data.

The Urbanism disequilibrium model developed by [Waddell \(2002\)](#) is representative of the second category. It recognizes that markets are not at equilibrium and analyses the dynamics of the evolutions of the system. It imposes no limit on the degree of agent heterogeneity it can handle. It jointly models the behaviors of households (choosing dwellings and car ownership) and individuals (making decisions relative to jobs and commuting). It is therefore adequate for targeting and for evaluating the redistributive effects of policies: who will react the most to such policies, who will benefit most from the different policies, in the short, medium, and long run? What are the long-run effects of those policies on individual and household well-being (on this topic, see [Antoniou and Picard, 2015b](#))? However, such disaggregate models requires very rich individual data, and they require significant effort to be implemented in a new region.

Egg, Chicken, Hen and Cock, or Family Economics

The chicken-and-egg problem becomes even more complex (and at the same time analyzed in a more realistic way and allowing more accurate public policy evaluation) when one recognizes the nature of the decision process within the family.

The decision tree described in the previous sections is simpler for a single man or woman than for a couple, with or without children. In the first case, the individual has to decide (jointly or sequentially) where to live, where to work, whether to own a car, how to commute, and which route to choose.

In the second case, the couple has first to agree on a common residential location, which is not easy when the man's current job or future job opportunities are typically located far away from the woman's current job or future job opportunities. Then each spouse has to choose job location and job position, which may include a trade-off between a well-suited job located in a place, which will induce long commutes and a poorly-suited job located close to the residence. See Chiappori et al. (2018) for a detailed analysis. The couple then has to agree on car ownership and on car usage by each spouse. When the couple decides to own only one car (which is common in many European dense cities such as Paris, London, or Stockholm), this induces a competition between spouses to use it. Picard et al. (2018) show that taking into account such interactions within the family significantly improves the estimation of individual values of time.

Conclusions

The chicken-and-egg problem is a very old philosophical problem, which raises specific questions not only in most disciplines of academic research, but also in public policy implementation and evaluation and in practice.

The problem is that we usually observe the word as it is today, and we wish to understand what are the causes, which led to the current situation. Usually, there are many suspects, and causality is at stake. Fortunately, several econometric tools have been developed, which help to disentangle a beam of causalities, which includes subtle ones, as the value of the initial conditions. For example, why do cars and trucks drive on the right side in some countries and on the left one in other countries?

The chicken-and-egg problem of interest in this article is related to major snowball effects governing long-run evolutions in transport and urban development. The improvement of the transport networks attracts population, firms and commercial activity from outside the region and concentrates population in the vicinity of new station or roads. The newly installed firms and households attract even more jobs, providing them inputs or services. And some firms are attracted by other firms, generating wider economic benefits.

The increased local demand for dwellings, offices and commercial buildings increases real estate prices (as well as congestion and pollution), which in turn induces promoters to increase the local supply of buildings, which itself real estate prices. The settlement of new households and firms increases transport demand up to a point such that new improvements of the transport network are required. Population and employment densification generates agglomeration effects and increases productivity, which attracts even more firms and highly qualified workers. All these processes are combined over space and time and the question is who is responsible?

Introduction

In this paper, we review the pricing principles as they apply in the transport sector. We focus on socially optimal pricing in first-best and various second-best environments. Although the general principles we discuss in this paper apply universally to all transport modes and transport services, we illustrate the main principles using road transport as our main example. We briefly discuss application to other modes in the concluding section.

In the remainder of this paper, we first explain first-best pricing principles. Next, we point at important restrictions on pricing instruments that prevent these principles to be applied. We then turn to a series of second-best pricing rules that take into account that pricing in the real world may not allow the required differentiation to implement first-best rules, and that it may be infeasible to implement optimal pricing for all transport services on the complete network. Before concluding, we briefly consider some additional complications.

First-Best Pricing: The Main Principles

The main principles of optimal transport pricing are based on the important work of Dupuit and Pigou in the 19th and the beginning of the 20th century. Ignoring issues of income redistribution for the time being and assuming that governments face no restrictions on the pricing instruments they can implement, the first-best pricing principle states that transport services should be priced at marginal social cost: the price of a transport service (a car trip, a freight shipment by rail, etc.) should capture the marginal production cost for the operator plus the full marginal external cost generated by the service. In the absence of externalities, pricing at marginal production cost is socially optimal because it makes sure users are willing to pay the extra production cost, so that price can fulfill its role as a signal of scarcity. Moreover, to signal to transport users that their transport choices generate undesirable side effects, socially optimal prices should also internalize all external costs of congestion, pollution, global warming, noise, and accident risks. The optimal price equals the marginal production cost plus a “tax” that captures the marginal external cost of the transport service.

It is instructive to derive the optimal tax in a simple framework; this also allows a better understanding of various second-best policies described later. Consider a transport service (e.g., the use of a particular road of given capacity during peak hours) for which the inverse demand function is given by:

$$P(X) = a - bX$$

The generalized price of use of the road consists of both monetary expenses (fuel, etc.) and time spent in traffic; this in turn depends on how much traffic X there is. We specify the generalized cost as:

$$g(X) = d + cX + t$$

In this expression, d is the money plus time cost when traffic can flow freely (literally, at a zero traffic flow), and c is the slope of the congestion function; it captures how the time cost increases when traffic levels increase. Finally, t is a congestion tax or toll (which of course may be zero).

Economists capture social welfare in this simple framework by gross consumer surplus minus the generalized price (which depends on the traffic level, hence, on congestion), plus toll revenues for the government, minus the external costs other than congestion; we assume here that all users drive the same type of car; the marginal external cost is constant and given by e . The first-best toll is then defined as the one that maximizes:

$$\int_0^X P(x)dx - g(X)X + tX - eX$$

Differentiating with respect to t and using the equality of the generalized price and generalized cost in equilibrium, straightforward algebra shows that the socially optimal toll is:

$$t = cX + e$$

The toll equals the marginal external cost of congestion (cX) plus the marginal external cost (e) of other externalities (pollution, etc.). The marginal external congestion cost of an extra trip is the effect of a marginal increase in the traffic flow on the time cost, multiplied by the traffic volume.

The earlier discussion holds for one given transport service; moreover, all drivers were assumed to have the same value of time, so that they all perceived the same generalized cost. Of course, in practice many different services can be distinguished (different times of the day, different roads, etc.), and drivers may be very heterogeneous in terms of their value of time. The principle of taxing marginal external costs then implies that first-best taxes should be differentiated in time and space, they should take into account the emission characteristics of vehicles, and they should reflect the heterogeneity in values of time.

The tax or toll should, as much as possible, vary with the level of congestion; as a minimum, it should be higher during peak times than in off-peak traffic conditions (analogous to peak-load pricing in, e.g., the electricity sector), and it should differ between different types of roads. Ideally, since congestion varies continuously over time, socially optimal pricing requires time-dependent charges in function of real traffic levels. The bottleneck model, developed initially by William Vickrey in the 1960s, has been intensively used to study such time-dependent tolling systems. It analyzes how congestion builds up and declines again over the peak period. Moreover, the model takes into account that people adapt their trip timing in function of expected congestion and that, next to a cost associated with time losses in traffic, there is also a cost of being too early or too late at the final destination. Application of the model shows that a time-varying (or “fine”) toll performs much better than the optimal uniform toll over the whole peak period. The socially optimal time-varying toll on a single road is zero at the beginning and end of the peak period, and the toll level closely follows real-time congestion levels. It eliminates all congestion but does leave a substantial scheduling cost (more precisely, the cost associated with having to travel at an undesirable time due to congestion) in equilibrium. Scheduling costs are of the same order of magnitude as the time costs of congestion (Arnott et al., 1993).

Moreover, the ideal tax should differ between vehicles to capture their exact marginal external cost of emissions. This would require the ability to directly measure and tax emissions for all vehicles. Due to the difficulties of directly taxing emissions the literature shows that, although pricing is an efficient instrument to deal with congestion (which for a given road capacity mainly depends on the traffic flow), other externalities such as pollution may be reduced more efficiently using regulatory instruments (emission restrictions on vehicles, etc.). Even if regulatory instruments are used, it should be noted that pricing remains necessary to deal with remaining external (mainly congestion) costs.

Finally, first-best pricing should take into account the heterogeneity in time values. If users have different alternatives to reach their destination, users with low time values will be channeled toward the slowest alternative. The first-best pricing rules are then straightforward extensions of those absent heterogeneity; the social optimum implies different tolls on the two alternative routes, with a higher toll on the faster route. However, it should be noted that the efficient pricing solution may be highly undesirable from an equity perspective; it may even increase travel times for people with low time values while still requiring them to pay a toll on the slower road (Verhoef and Small, 2004). As always in economics, efficient outcomes are not necessarily equitable.

The first-best principle of marginal social cost pricing applies to all transport services, including road transport, rail service, airport use, etc. Of course, applying the principles requires taking into account the specific characteristics of the transport service considered.

Imperfect Pricing Instruments

Many currently used price instruments (fuel taxes, kilometer charges, and cordon pricing) do not allow policy-makers to sufficiently differentiate in space and time or according to vehicles’ emission characteristics. In [Table 1](#) we summarize the effect of some frequently used price instruments on the different external costs of transport. In the last column, we comment on the ability of the instrument to differentiate according to congestion and environmental externalities.

Restrictions on instruments necessitate second-best deviations from the marginal social cost pricing principles outlined earlier. Moreover, deviations from first-best pricing also apply in many practical instances when governments can only tax some, but not all, transport services. We briefly discuss a number of relevant second-best pricing rules, using a simple model with linear demand and generalized costs as illustration.

Table 1 Effect of pricing instruments on external costs

Price instrument	Effect on congestion	Effect on environmental externalities	Effect on accident risks	Impact on government revenues	Comments
Electronic road pricing	++	+	+	++	First best if differentiated in time and space
Fuel taxes	+	++	0	++	No time differentiation; allows differentiation between fuel types and fuel efficiency
Kilometer charges	+	+	+	++	No time differentiation, no fuel type differentiation
Cordon pricing	++ (in cities only)	+	+	+	No differentiation according to distance, inappropriate regional differentiation
Parking charges	+	+	+	+	Very imperfect instrument to deal with congestion; little effect on emissions
Public transport subsidies	+	+	+	--	Cost of funds, second best
Ownership taxes	0	+ if differentiated to emission characteristics	0	0	Little effect on congestion, poorly related to external costs
Subsidies to clean vehicles	0	++	0	--	Costly policy, no congestion effects

Second-Best Pricing I: Uniform Pricing

Uniform pricing instruments such as fuel taxes and distance-related taxes (kilometer charges) do not allow appropriate differentiation in time and space and according to vehicle type. For purposes of concreteness, consider a setting with two time periods (e.g., peak and off-peak) with clearly different marginal external costs. Assume that the government wants to set a socially optimal uniform tax per kilometer, that is, an equal tax in both periods. To capture differences in congestion between periods of the day on a given road infrastructure, it can be shown that the optimal tax per kilometer can be written as a weighted average of the marginal social costs in the two periods. The weights reflect the relative price elasticities of demand in the two periods. To minimize distortions, the common variable price will be closer to the marginal social cost in a given period the larger the relative price sensitivity of demand in that period.

To illustrate the pricing rule, denote the peak and off-peak by subscripts p and o , respectively. Linear demands in the two periods are $P_i(X_i) = a_i - b_i X_i$; $i = p, o$. Let generalized costs be given by:

$$g(X_i) = d + cX_i + \tau; \quad i = p, o$$

Here, τ is the uniform toll per kilometer in both periods. Ignoring noncongestion externalities for simplicity, the optimal toll solves:

$$\text{Max}_{\tau} \int_0^{X_p} P_p(x_p) dx_p + \int_0^{X_o} P_o(x_o) dx_o - (g(X_p))X_p - (g(X_o))X_o + \tau(X_p + X_o)$$

One then shows that the optimal uniform toll is given by:

$$\tau = s_p(cX_p) + (1 - s_p)(cX_o)$$

where the $0 < s_p < 1$ (more precisely, $s_p = \frac{\epsilon_p X_p}{\epsilon_p X_p + \epsilon_o X_o}$; $\epsilon_i = \frac{\partial X_i}{\partial \tau} \frac{\tau}{X_i}$, $\frac{\partial X_i}{\partial \tau} = -\frac{1}{c + b_i}$). This shows the optimal time-independent toll is a weighted average of the relevant marginal extern congestion costs; the weights depend on the price sensitivities of peak and off-peak demands with respect to the toll.

Similar pricing rules govern the optimal uniform tax when the same tax applies to two types of vehicles that differ in emissions per kilometer. Consider for concreteness the optimal fuel tax, when different vehicles have different emission characteristics. Similar analysis shows that the optimal tax is a weighted average of the external costs of different cars, where the weights depend on the sensitivity of the demand for car use of each type with respect to the tax. The implication is that, if "dirty" cars are more price sensitive than "cleaner" cars then the optimal uniform tax should be higher.

Finally, as will be argued later, due to the strong complementarity of commuting transport and labor supply, governments may want to impose a lower tax on commuting transport than on noncommuting transport. Here again the same principle applies: the inability to differentiate tolls according to trip purposes implies a uniform toll on both commuting and noncommuting that is a weighted average of the optimal differentiated tolls.

Second-Best Pricing II: Not All Transport Services Can Be Priced

In many practical cases, deviations from first-best principles apply because it is not feasible to optimally tax all transport services. Suppose, for example, that only a subset of roads (highways, some major roads) can be tolled. Alternatively, some governments may want to tax freight, but not passenger, transport. Finally, one may wonder how public transport should be priced depending on whether or not car use is charged for external congestion and pollution costs.

Only Part of a Network Can Be Priced

Very commonly governments cannot toll the complete network but are limited to charging tolls on a subset of important roads. Several cases can be distinguished here.

First, consider a simple network of two parallel roads between an origin and a destination, one of which can be tolled while the other remains un-tolled. This may be due to technical difficulties when tolling the whole network, or it may be deliberate government policy: in some countries (e.g., France) tolling requires an available un-tolled alternative. A major insight is that the optimal toll on the tolled road equals the marginal external congestion cost on that road minus a fraction of the marginal external congestion costs on the un-tolled one. If congestion costs on the un-tolled road are severe, this may easily result in a negative (in practice, a zero) toll.

To illustrate, assume two roads connect a given origin and destination (e.g., two cities); the roads may differ in capacity, design, etc. Denote the tolled road as A , the un-tolled alternative as road B . The demand for trips between the two cities is given as:

$$P(X) = a - bX; \quad X = X_A + X_B$$

Generalized costs of the two alternatives are, where the toll on road A is denoted t_A :

$$g_A(X_A) = d_A + c_A X_A + t_A$$

$$g_B(X_B) = d_B + c_B X_B$$

When people select a route only in function of the generalized cost, the equilibrium conditions are:

$$a - b(X_A + X_B) = d_A + c_A X_A + t_A = d_B + c_B X_B$$

which imply the following:

$$\frac{dX_A}{dt_A} = -\frac{(b + c_B)}{\Delta} < 0; \quad \Delta = b(c_A + c_B) + c_A c_B > 0$$

$$\frac{dX_B}{dt_A} = \frac{b}{\Delta} > 0$$

The toll reduces demand on the tolled road and diverts traffic to the un-tolled road. Focusing on congestion externalities only, we solve:

$$\text{Max}_{t_A} \int_0^X P(x) dx - (g_A(X_A))X_A + t_A X_A - (g_B(X_B))X_B$$

We find the optimal toll as:

$$t_A = (c_A X_A) - \delta (c_B X_B); \quad 0 \leq \delta = \frac{b}{b + c_B} \leq 1$$

The toll on road A is below the marginal external congestion cost on that road; setting the toll lower limits diversion of traffic toward road B , which is not tolled but becomes highly congested when many drivers try to avoid the toll on A . How much the toll should be below the marginal external cost depends on the price sensitivity of demand for the use of road A (captured by the parameter b) and on the slope c_B of the congestion function in B . If demand is very elastic (b small, so that δ is small) then a small reduction in the toll on road A is sufficient to limit traffic diversion toward the un-tolled road. On the contrary, if demand is not price sensitive (large b , hence large δ), a much larger toll reduction on road A is needed to prevent too much traffic diversion toward road B . Moreover, the earlier expression implies that if congestion on B is severe it may actually be better not to toll road A at all: the optimal toll can easily become zero or negative. To see this note that, if c_B becomes large, the second term in the earlier expression may exceed the first one for two reasons: the marginal external congestion cost $c_B X_B$ on road B becomes large, and δ approaches one. It does not make sense to toll road A if the main effect is to cause very much congestion on road B .

The earlier example was very stylized, and it has been generalized in different dimensions. One extension considers a general network consisting of an arbitrarily large number of nodes and links, where some but not all of the links can be tolled. The second-best optimal toll on a given link should then be a weighted average of the sum of the generalized marginal external costs, minus the

tolls paid on other links, for the relevant path flows. The weights are increasing in the elasticity of the path flow to prices in the second-best optimum. Another extension accounts for heterogeneity in time values. This does not affect the finding that the toll is less than marginal external cost. A final extension is to use a bottleneck approach and allow for time-varying tolls. In a setting with homogenous drivers using a network that consists of a tolled road and an un-tolled alternative (say, a two-lane highway with a toll-free lane), optimal second-best pricing implies a time-varying toll on the pay lane, combined with a subsidy that does not depend on time. Intuitively, the time-varying toll is imposed to eliminate queuing, and the subsidy is granted to attract users to the road whose capacity is efficiently used. In the absence of the subsidy, the pay lane has lower social marginal costs. This makes it desirable to attract drivers from the free lane, hence the subsidy also. Allowing for heterogeneity in time values does not affect these main principles.

Second, another example of partial pricing occurs when cities implement cordon tolls, whereby drivers pay a toll when entering a well-defined cordon around the city center. In this case, part of the network (namely, the area outside the cordon) remains unpriced. To illustrate the implications for the optimal cordon toll in the simplest possible way, suppose that some people commute from the suburbs to the city center. Denote their demand for trips by X . These people all drive into the city cordon but also use the un-tolled suburban network. A second group of commuters lives closer to the city; they only use the city network but not the suburban roads. Denote their demand by Y . Let the inverse demand functions be:

$$P^X(X) = a_X - b_X X; P^Y(Y) = a_Y - b_Y Y$$

Generalized costs of using the city (subscript “city”) and suburban network (subscript “suburb”) are given by, respectively (the cordon toll is denoted τ_c):

$$\begin{aligned} g_{\text{city}}(X + Y) &= d_{\text{city}} + c_{\text{city}}(X + Y) + \tau_c \\ g_{\text{suburb}}(X) &= d_{\text{suburb}} + c_{\text{suburb}}X \end{aligned}$$

Equilibrium requires:

$$\begin{aligned} P^X(X) &= g_{\text{city}}(X + Y) + g_{\text{suburb}}(X) \\ P^Y(Y) &= g_{\text{city}}(X + Y) \end{aligned}$$

As expected, the effect of the cordon toll on both types of demand is negative; we find:

$$\begin{aligned} \frac{dX}{d\tau_c} &= \frac{-b_Y}{\Delta} < 0; \quad \Delta = (b_X + c_{\text{suburb}})(b_Y + c_{\text{city}}) + c_{\text{city}}b_Y > 0 \\ \frac{dY}{d\tau_c} &= \frac{-(b_X + c_{\text{suburb}})}{\Delta} < 0 \end{aligned}$$

Maximizing welfare, we solve:

$$\int_0^X P^X(x) dx + \int_0^Y P^Y(y) dy - (g_{\text{city}}(X + Y))(X + Y) - (g_{\text{suburb}}(X))X + \tau_c(X + Y)$$

The optimal cordon toll can be derived as:

$$\tau_c = c_{\text{city}}(X + Y) + c_{\text{suburb}}X \left(\frac{b_Y}{b_Y + b_X + c_{\text{suburb}}} \right)$$

The toll exceeds the marginal external congestion cost in the city. The reason is that it also corrects for the un-tolled suburban road; it includes a fraction of the marginal external cost on the suburban road, too.

Not All Modes Can Be Optimally Priced

When multiple modes are considered, not all of which can be optimally priced, the same principles hold as in the case only part of the network can be tolled. Consider, for example, the competition between car and public transport use. Denoting the two modes as A and B this is conceptually the same problem as the two-road problem discussed before. If for some reason car use does not appropriately charge for external congestion costs, then it is second-best optimal to also price public transport below its social cost. We return to public transport pricing later.

Pricing Only Freight (But Not Passenger) Transport

In some countries it has been politically difficult to optimally toll both passenger and freight transport. If only freight can be taxed, what is the optimal tax to be implemented? Higher taxes on freight transport will typically raise the demand for passenger

transport: freight taxes reduce demand for freight, reducing congestion and attracting more passenger cars. Under plausible conditions, if passenger transport does not fully pay its marginal external costs, then the optimal toll on freight transport is below its marginal external cost as well. Still, only raising the tax on freight transport (but not on passenger transport) will be a good idea from a welfare perspective, unless passenger transport is severely under-taxed and the tax reform attracts substantially more passenger transport.

Pricing of Public Transport Services

In the absence of first-best pricing on congestible roads, reducing public transport fares below marginal social cost can be a legitimate second-best policy. The general idea that public transport can serve as a tool to alleviate the deadweight loss of suboptimally priced road congestion is by now widely documented, and large optimal subsidies have been reported. The standard second-best argument for lower than social cost prices is reinforced by the marginal benefits resulting from Mohring effects: low fares stimulate demand and this induces operators to raise frequency; this generates an external benefit in that it reduces passengers' average waiting times at public transport stops.

However, there are several caveats to this result. First, the argument is only relevant if the cross price elasticity of the demand for car use with respect to the public transport fare is sufficiently large relative to the own price elasticity of public transport demand. Second, public transport is subject to on-vehicle crowding: this increases boarding time, slowing travel speed; it also causes discomfort to others, and this disutility implies that public transport users generate a negative externality for other users. Third, governments may be willing to charge car use for its external congestion costs. When private transport is optimally priced, public transport pricing should be based on the same principles as pricing for road use. This implies that the second-best argument for low fares disappears, and fares therefore should also take into account the marginal external cost of an additional user. When road use is correctly priced and there is important crowding in public transport, the need for large subsidies is therefore much less clear. For example, evidence suggests that congestion pricing and dedicated bus lanes (absent bus subsidies) are much more efficient than bus subsidies ([Basso and Silva, 2014](#)). Some studies even find that even at current (too low) road charges, it is best to increase peak period prices of public transport on some highly crowded links. Moreover, fares should be increased in general whenever road pricing is put in place. Some studies argue that crowding implies that during peak and off-peak periods it is strongly welfare enhancing to differentiate public transport prices and vary frequency of service. Peak pricing helps to cover the costs of supplying capacity. When peak prices are too low, there is an excess demand for capacity and with a low revenue base it is difficult to improve or expand public transport services. The best overall transport policy reform includes higher toll levels on car use, higher peak bus fares and frequency, and free off-peak bus services offered at lower frequencies. These policies therefore definitely do not necessarily imply higher bus subsidies.

Some Further Complications

Commuting Transport and the Labor Market

Many congestion problems are due to commuters driving to work. The question arises whether commuting should, for this reason, be treated differently than other trip purposes. The literature suggests that the desirability of charging marginal external congestion cost to drivers and allowing toll reductions for commuters depend both on the sensitivity of labor supply with respect to the toll and on the distortive effects of existing labor taxes ([Van Dender, 2003](#)). If labor taxes are too high from a social perspective then it is optimal to differentiate tolls on commuting and other trip purposes, with lower tolls for the journey-to-work. This holds both for car and bus travel. Depending on the level of the labor tax relative to its socially optimal value, it may be optimal to not toll commuting at all. If labor and transport taxes are jointly optimized, transport taxes on car use increase substantially; commuting is still taxed somewhat lower than other trip purposes.

These findings do not justify general subsidies to commuting. They justify commuting subsidies (in the sense of lower tolls compared to other trip purposes) only on condition that congestion is taxed and given that current labor taxes are higher than socially optimal. Absent congestion charges subsidies for commuting are strongly welfare-reducing. These results generally hold both with competitive and imperfectly competitive labor markets (e.g., in a setting where wages and/or employment are determined by bargaining between unions and employer organizations).

Distributive Issues

There is some discussion whether distributive issues should matter for setting optimal transport prices. A standard partial equilibrium result is that, conditional on external costs and price elasticities, services used to a large extent by relatively low-income groups may be priced at a lower rate. However, general equilibrium models capturing the link between transport and labor markets suggest that the level of the externality tax does not depend strongly on distribution concerns, as re-optimization of the other taxes available to the government ensures that the income distribution objective is reached.

Conclusions

In this paper, we very briefly reviewed some important principles of socially optimal pricing of transport services. Although we illustrated these principles mainly for road transport, first-best and second-best pricing rules based on marginal external costs apply to all transport services, including road transport, rail service, airport use, etc. In practice, applying the principles does require taking into account the specific characteristics of the transport service considered. Ports and airports are part of a logistic chain, and external costs may be associated with each part of the chain (e.g., hinterland congestion); rail stations and airports have limited slot capacity, and congestion may strongly depend on slot allocation mechanisms.

Finally, given distortions elsewhere in the economy, it should be noted that the welfare effects of optimal pricing strongly depend on the use of the revenues. This also largely determines the political acceptability of optimal pricing schemes (De Borger and Proost, 2012). Take road pricing as an example. Many drivers will be worse off, and unless the revenues are used to partly compensate them and to offer good alternatives (better public transport, biking paths, etc.) to road use, proposals for the adoption of optimal prices will be rejected.

Introduction

Monetary valuations of travel-related attributes are crucial inputs to appraisals of infrastructure investments. In particular, the valuation of travel time savings, which indicates how much travelers are willing to pay for reducing travel time, is often a strong determinant of the benefits associated with infrastructure investments, as travel time gains usually constitute a major share of the expected economic benefits (Small, 2012). Other valuations relevant for appraisals are valuations of schedule delays, reliability, and comfort.

This chapter discusses the evidence for a divergence between valuations depending on the time frame during which travel behavior can be adjusted, and discusses possible implications and avenues for further research. Recent literature has provided evidence that travel-related valuations may depend on the temporal dimension of the underlying decision. For instance, valuations may depend on whether a travel time saving occurs only on a specific day without notification (short-run), repeatedly (medium-run), or permanently (long-run) (e.g., Peer et al., 2015; Beck et al., 2017; Peer and Börjesson, 2018).

Most transport policies and investments lead to permanent changes to which users can adapt to over long time spans. In contrast, most valuations are derived from hypothetical choices made in situations (Peer and Börjesson, 2018) with a short-run framing, leading to a divergence between short-run and long-run valuations, which have immediate policy implications. Choosing the right valuations as inputs for appraisals is crucial for obtaining unbiased results. Dependency of valuations on the temporal dimension may also explain to some extent why the valuations of trip-related attributes vary so widely across studies and data sources.

The section “Distinguishing between short-run, medium-run and long-run choices” provides an overview on how short-, medium-, and long-run choices can be distinguished, and how they are reflected in the available literature. Section “Empirical evidence on differences in valuations depending on the temporal scale” summarizes the relevant empirical findings regarding the temporal dimension being able to explain differences in valuations. Also alternative explanations for divergent findings are discussed. Section “Implications” discusses the implication of the findings. Section “Discussion and outlook” summarizes and provides some avenues for further research.

Distinguishing Between Short-Run, Medium-Run, and Long-Run Choices

Definitions

Travel-related decisions can be categorized along multiple dimensions. One dimension is the temporal dimension of a specific decision, or more precisely, the time frame during which behavior can be adjusted.

In models of industrial organization, the long run is defined as the time frame when all input factors are variable (often defined as time spans exceeding 5 years), whereas in the short run it holds that at least one input factor is fixed. Similarly, in the travel context, the long run can be defined as the time frame in which persons have the flexibility to change all travel-related attributes, most importantly the duration of the commute. Primarily, they can do so by changing their home location or work location, but also buying a car (if they have not owned one before) may have a similar effect. These decisions are not easily reversible and can under normal circumstances not be changed in the shorter run.

The medium run can be defined, as the time frame in which the outcomes of the long-run choices are fixed, while other decisions, most importantly travel routines and times for meetings that can be irregular, are still endogenous. Travel routines may for instance concern the usual schedule for the commute from home to work (and vice versa), but also a more general activity plan, which includes trip chains, such as dropping off and picking up children at/from school on the way to work. Routines may, for instance,

also refer to the usual transport mode used for a specific trip purpose. The medium run is often defined as a timeframe of more than 1 year but less than 5 years, however, depending on the context alternative delineations of the medium run from the short and long run may be more useful.

In the short run, not only the outcomes of the long-run choices but also the travel routines chosen in the medium run are fixed. Individuals thus have already made an activity plan for a specific day, and then decide on their day-specific travel behavior subject to the long- and medium-run decisions they have made. Short-run decisions are thus usually defined such that they concern a specific trip (or trip chain); for instance, a short-run decision may concern scheduling aspects (choosing for a specific departure and/or arrival time, respectively), route choice or a choice between competing transport modes. Deviations of short-run decisions from routines are often driven by updated information regarding travel time expectations (Peer et al., 2015). Short-run deviations from medium-run choices thus occur primarily if day- and/or trip-specific factors play a role. For example, bad weather or special events may raise the expectation of longer travel times for the commute. In order to still arrive at the usual arrival time at work, a person may then decide to depart earlier than usual from home. Persons are expected to trade-off the benefits resulting from deviations from their medium-run choices (e.g., routines) against the costs of the deviation from the routine.

A distinction between long-run, medium-run and short-run time frames in travel-related decisions is also consistent with findings related to the relevant demand elasticities, for instance, concerning fuel prices or transit prices: these elasticities tend to increase (in absolute terms) over time, as travelers become more flexible (Litman, 2004) in adjusting decisions. Long-run transit elasticities have been found to be 2–3 times higher than the corresponding short-run elasticities.

Finally, it should be noted that the distinction between long-, medium-, and short-run decisions is not uniquely defined, but can be context specific. For instance, the housing choice might be a medium-run choice for many students (who tend to be fairly flexible), but constitutes a long-run choice for most families.

Literature

There exists a wide body of empirical literature on short-run travel choices, such as route, departure time, and mode choices for a specific trip. They yield monetary valuations by including trade-offs between a monetary component and other attributes. In the last decades, most of valuation studies have been based on stated preference (SP) data, and hence on hypothetical choices. Although these SP studies often do not make the short-run framing explicit, the choice context tends to be implicitly short-run, as respondents are asked to consider a specific trip in their choices, including the applicable scheduling constraints and activity schedule planned for that day. This is especially true for studies published in the past decade, many of which are driven by the idea that framing SP experiments around a specific reference situation (referencing) renders it easier for respondents to take into account (scheduling) constraints. In turn, the SP choice situations are expected to be more realistic and thus easier to answer for respondents, in turn reducing the presence of hypothetical biases. This reasoning has, however, been disputed in more recent studies (e.g., Hultkrantz and Savsén, 2018). Moreover, as argued below, the “referencing” approach and the resulting short-run re-scheduling and reference-dependence might be leading cause of divergence between short-run and long-run valuations.

Medium-run choices, in particular the choice of travel routines, have received comparatively little explicit attention in the transport economics literature. Travel routines have mostly been discussed in the context of (transport) psychology, where routines are often being characterized by little deliberation rather than the outcomes of a conscious choice process, implying that the underlying trade-offs based on which valuations can be derived have rarely been modeled explicitly. Only recently, it has been shown that also routines follow a rationale that allows for the derivation of valuations. For instance, the usual arrival time at work has been shown to result from the trade-off between regular (time-of-day-specific) travel times and schedule delays relative to an intrinsically (long-term) preferred arrival time (Peer et al., 2015). Although often not explicitly referred to as medium-run valuations, it can be argued that valuations derived from revealed-preference (RP) data, for instance from trip diaries, may reflect medium-run behavior (e.g., Schmid et al., 2019). Such data often reflect the usual, equilibrium behavior of individuals in situations where long-run choices are fixed. So far, only few SP studies have explicitly adopted a medium-run perspective, for instance by explicitly stating that the choice concerns a regular trip and that the choice will only be effective at some point in time, rather than immediately. The lack of such SP studies may be related to difficulties to ensure that respondents indeed interpret the choices as intended by the designer of the SP experiment: they may ignore the medium-run context and fill in the choice experiment as if it referred to a specific trip on a specific day.

Long-run choices regarding residential and workplace location as well as car ownership have been researched extensively. Most of them find that commuting time has a significant effect on residential and employment choices. The same holds for other transport-related factors, such as the availability of alternative transport modes at the home location. The effect of travel-related factors on long-run decisions has been shown both in situations with real-life data as well as in SP choice experiments that present for instance trade-offs between wage rates and commuting time, or between characteristics of the residential/workplace location and transport-related attributes (e.g., Van Ommeren et al., 2000). Although for similar reasons as discussed in the context of medium-run choices, SP experiments are not very common. In SP experiments with a long-run framing (and to a lesser extent also in experiments with a medium-run framing) it is also uncertain how respondents interpret changes in (travel-related) costs and/or revenues (salary), in particular because income effects as well as discounting may play a role.

Empirical Evidence on Differences in Valuations Depending on the Temporal Scale

In general, evidence on differences between short-run and longer-run valuations can be derived from unrelated studies that investigate transport-related choices in different time frames. However, due to the presence of a large number of potentially confounding factors, we focus on evidence derived from studies that make a direct comparison between short-run and longer-run valuations, but we additionally provide evidence from indirect comparisons when useful.

The following paragraphs attempt to summarize some patterns that have become evident in the relevant literature. These in particular concern travel times and to a lesser extent schedule delays and reliability. Given the limited number of studies and their heterogeneity in terms of research design (among others, regarding the underlying data source, transport mode, decision type and definition of the time frame), results cannot be regarded yet as conclusive.

The main result that can be generalized across most studies that directly compare short-run and longer-run valuations is that travel time is valued higher in a longer-run context (such as the medium-run choice of a travel routine, or the long-run trade-off between wage rate and commuting time) compared to a short-run context (including trip-specific departure time and mode choices) (Peer et al., 2015; Beck et al., 2017; Peer and Börjesson, 2018). Also a comparison between SP- and RP-based valuations of travel time savings that have been elicited in a similar context, sometimes even by the same travelers, yields a pattern consistent with long-run valuations of time being higher: RP data, which tend to reflect longer-run equilibrium situations, tend to imply higher valuations than SP data, which usually have a short-run focus as discussed earlier. A plausible explanation for the higher travel time valuations in the long run may be that the time gained from reduced travel time can be used more productively when arrival and departure times are known well in advance and if the travel time reduction occurs on a regular basis. It is realistic to assume that a small, unexpected, one-off time gain in the short run is more difficult to use productively, as travel time cannot be accumulated and saved (unlike money) compared to an expected, repeatedly occurring time gain of the same size.

The lower short-run values of time are also consistent with short-run rescheduling efforts with respect to a (short-run) reference point, introduced by the short-run framing of most SP experiments (Peer and Börjesson, 2018). This is particularly true if respondents are asked to make their choices while thinking about a specific trip, including the time constraints and activity schedule planned for that day. Short-run re-scheduling and the related reference-dependence are both undesirable, as they shed strong doubt on respondents answering to SP questions in a way that uncovers their long-run reference-free stable preferences, which are essential for economic welfare analysis. This is particularly important, as usually the objective of eliciting the preferences of respondents is to obtain valuations for investments and policy appraisals with a long time horizon.

The existing evidence for schedule delays and reliability is more mixed. In some studies, schedule delays and reliability are found to be valued higher in the short run, possibly reflecting that scheduling restrictions tend to be more binding in the short run, and re-scheduling is costlier (e.g., Peer et al., 2015). Other studies have found the opposite pattern, bringing forward similar arguments as for the higher value of time in the long-run context (Peer and Börjesson, 2018). Unreliability in the long-run context may also be higher due to it causing more anxiety over a longer period of time.

A general observation is that studies comparing shorter- and longer-run valuations based on SP data may have shortcomings regarding the comparability of the valuations. These are also brought forward by the authors of these studies, who in some cases provide alternative explanations for their findings, indicating that the differences in valuations may be attributable to other factors than the temporal dimension. For instance, the sensitivity to the cost component, which may also vary between the short run and the long run, may at least partially drive differences in valuations. Differences in the sensitivity to money over time can, however, rarely be distinguished from the response scale, which may also differ between short-run and long-run experiments, but without a clear a-priori expectation whether it is higher in SP experiments with a short-run framing or those with a long-run framing: reasons for a lower response scale (and hence for choices being less deterministic from analyst's point of view) in short-run experiments may be that they are difficult to answer, in particular if they require short-run rescheduling. Longer-run experiments may have a lower scale as long-run decisions are taken only at a low frequency and respondents may hence be less familiar with the corresponding trade-offs. Moreover, long-term decisions are potentially affected by a multitude of different factors, which cannot all be included in a standard SP experiment, leading to a larger random component.

Implications

The evidence of differences between short-run, medium-run, and long-run estimates (in particular, of the value of time) implies that preferences may not be stable in time, which is problematic as stable preferences are a key assumption in welfare economics. Most transport policies and investments tend to have long time horizons of several decades, for which long-run, reference-free stable preferences are the relevant input. This is in stark contrast to the fact that most recent valuation studies are based on SP experiments that adopt a short-run framing, and are hence likely to also elicit short-run valuations. This suggests a mismatch between the way the valuations are derived and their usage in appraisals. More precisely, it suggests that valuations used in the appraisal of policies and investments should reflect whether they lead to permanent changes (e.g., road capacity expansions, construction of new routes) or whether changes occur only under certain circumstances (e.g., improvements in incident management).

Differences in valuations between short-run and longer-run choices may also have implications for the optimal design of transport policies. For instance, pricing instruments required to reach the social optimum have been shown to differ considerably

from the standard (short-run) solution of the bottleneck model once the distinction between a medium-run choice of travel routines and short-run scheduling preferences regarding departure times is taken into account (Peer and Verhoef, 2013).

Discussion and Outlook

The earlier discussed summary of the relevant literature has shown that short-run and longer-run valuations of travel attributes have been found to diverge. In particular, valuations of travel time tend to be higher (Beck et al., 2017; Peer and Börjesson, 2018) in the longer run. This has been shown in SP studies that compare valuations elicited in experiments with a short- and long-run framing. Also indirect evidence from studies that compare valuations derived from SP data, with the underlying experiment typically having a short-run focus, to those derived from RP data, which tend to represent a more longer-run equilibrium situation. Evidence for other attributes (schedule delays, reliability) is quite mixed.

The direct comparison between short-run and longer-run valuations has only gained interest by researchers in the past few years. So far, only a limited number of studies that focus on such a comparison have been published. They differ widely in terms of the underlying research design, including data source (SP vs. RP), decision type (scheduling choice; trade-off between time and cost; etc.) as well as the main transport mode (car, train) considered. As a result, the evidence on differences between long-run and short-run valuations is not conclusive.

The limited number of studies and the (at least partially) inconclusive results render the topic of this chapter an interesting and promising avenue for further research. First, future research should focus on confirming the validity of the results obtained in the existing literature by replicating existing approaches and testing whether they also hold in different contexts. Second, also methodological advancements are required. In particular, it would be important to develop research designs that have a high comparability between short-run and long-run designs. For SP-based studies, the main challenge remains to phrase and frame the experiments such that respondents interpret the choice situations in the same way as intended by the researcher (hence, either as long-run or short-run choice) and react to it as they would react in reality. The latter is of course a more generic concern related to SP data, including data that are collected for the analysis of travel behavior. In particular, the medium- and long-run framing of choices is an important avenue for future research, as most existing SP experiments adopt a short-run framing. It is challenging to design SP experiments such that they closely reflect the complex decision processes underlying, in particular, long-run decisions regarding residential and work location.

Once evidence on differences in valuations depending on the time frame of the underlying decision has converged, differences in valuations across time dimensions may also inform theoretical and simulation studies on the optimal design of policies. For instance, most of these models so far assume that successive days are replicas in terms of travel times, implying that medium-run choices of routines and short-run choices of departure time are identical and cannot be disentangled. The same is true for stochastic models when they assume that travel time expectations are constant across days, and hence no learning or expectation updating takes place (Peer et al., 2015). Also in this case, short-run choices will not change between days, and again, medium-run and short-run behavior coincides.

In the relevant literature, different time horizons of travel-related decision making have mostly been considered separately, despite the underlying inter-temporal optimization that travelers engage in. A reason for the lack of models that represent such inter-temporal optimization processes may be the inherent complexity of these processes. Future research should aim at yielding a better understanding of the inter-temporal dynamics that travel choices are based on, making explicit, how these dynamics affect the travelers' response to transport, but also environmental and land-use policies, and in turn, the characterization of appropriate first- and second-best policies. Ignoring the embedment of most decisions in a wider framework of decisions across inter-temporal dimensions might lead to wrong conclusions regarding policy design and appraisal.

Glossary

A-weighted decibel (dBA) Weighted measure of decibels that accounts for the fact that the human ear is less sensitive to low-frequency sounds.

Coase's theorem The proposition that market trade will solve externality problems provided property rights are sufficiently well defined and enforceable, and negotiation or bargaining is not limited by high transaction costs.

contingent valuation (CV) Survey-based method for valuing market and nonmarket resources such as environmental quietude obtained by asking people to state their willingness-to-pay for more of a specified resource or willingness-to-accept less of a specified resource.

day-evening-night sound level (L_{den}) Average equivalent sound level exposure over a 24-h period with a 5-dBA penalty added for the evening hours of 19:00–22:00 and a 10-dBA penalty added for the nighttime hours of 22:00–07:00. Also called the community noise equivalent level or CNEL.

day-night sound level (DNL) Average equivalent sound level exposure over a 24-h period with a 10-dBA penalty added for nighttime hours of 22:00–07:00.

decibel (dB) Unit used to measure or compare the intensity of sound on a logarithmic scale, with the capital “B” included in recognition of Alexander Graham Bell.

hedonic price (HP) Measure of the implicit monetary value of characteristics or attributes that comprise a resource such as the implicit price or willingness-to-pay for the absence of noise as embodied in the market price of a house or apartment.

noise depreciation index (NDI) Method of expressing the effect of noise on property values or apartment rents when measured as the percentage reduction in value for each additional decibel increase in noise exposure.

Schultz curve Relationship between level of noise exposure and percent of the exposed population that is highly annoyed. First proposed and derived by acoustician Theodore Schultz in 1978.

stated preference (SP) method Survey-based methods for determining the monetary value of nonmarket resources such as expressed by contingent valuation surveys.

willingness-to-accept (WTA) Monetary measure of the minimum compensation required to forego a resource or accept a price increase. As a lump-sum amount, it is the compensating variation or increase in income required to accept a change in the status quo.

willingness-to-pay (WTP) Monetary measure of the maximum amount offered to obtain a resource or forgo a price increase. As a lump-sum amount, it is the equivalent variation or decrease in income required to avoid a change in the status quo.

Overview of Noise Cost Valuation

Noise is unwanted sound and vibration. Although by no means the only source, transportation is the dominant source of noise in areas near highways, major streets, railroads, and airports. Noise is an uncompensated cost to property owners and bystanders or, in the language of economics, an external cost of market activity. Costs are incurred by occupants of residential properties and others in the form of annoyances such as sleep disturbance, speech interference, disrupted outdoor activities, productivity losses at school and work, and possible health effects such as stress and loss of hearing. Prior to the early 1970s, noise was viewed generally as an environmental

nuisance to be dealt with by local and state authorities and the courts. The shift to more centralized control is illustrated by federal legislation in the United States such as the Airport and Airway Development Act of 1970, Federal-Aid Highway Act of 1970, Noise Control Act of 1972, and the Quiet Communities Act of 1978. Federal legislation requires application of social benefit–cost analysis as the basis for environmental decision-making. Early attempts to value noise in the context of benefit–cost analysis began with the Roskill Commission on the Third London Airport (1968–70), which leads to debate among economists on the definition and valuation of noise costs (Waters, 1975). In recent years, noise valuation has expanded to include considerations of access to transportation networks and related employment, environmental justice, and efficiency of markets for real estate. Consider the economic and political issues associated with a localized improvement project such as expansion of a major highway, rail line, or airport. Users of transportation incur benefits in terms of improved access, vehicle cost savings, and safer or more reliable travel. Secondary or community-wide impacts also may occur such as employment gains, pecuniary changes in prices of related commodities, changes in market competition, and economic growth, but these effects are transfers in the context of a social benefit–cost analysis. Costs of improvements include direct resources used for expansion and any uncompensated external costs that continue after project completion, including increased noise exposure. How should negative externalities be measured and valued? What is the willingness-to-pay for noise abatement? What is the willingness-to-accept compensation for increased exposure to noise? Absent an explicit market for quietude, economists have developed two main methods to value external costs from transportation noise. Revealed preference methods use observed changes in market prices of complementary resources such as the market for residential property. Primary studies using this method are labeled hedonic price (HP) studies, where “hedonic” refers to implicit values attached to attributes of housing such as environmental quiet. Stated preference methods use people’s responses to survey questions regarding willingness-to-pay for hypothetical changes in living conditions or changes in specific activities such as hiking in a public park that is free from overflights by aircraft. Primary studies using this method are labeled contingent valuation (CV) studies, where a survey is used to create an artificial market within which individuals purchase more or less of environmental services contingent on hypothetical prices. Both empirical methods have long histories in economics and both have advantages and disadvantages for valuation of transportation noise.

Hedonic Property Value Studies of Transportation Noise

Suppose a house or apartment is either located in a noisy residential neighborhood or it is not. The current level of noise is easily noticed or experienced by all market participants, but there may be uncertainty about future levels. The difference in values of identical residences in the quiet versus noisy neighborhood yields an implicit cost of noise, which is capitalized into the market value of houses or revealed by differences in monthly apartment rents. In principle, the discount attributable to noise compensates residents of noisy houses and apartments. That is, informed market participants reveal the value of noise as a result of bids and offers in the market for real estate after accounting for quality differences among properties. The sorting of buyers and sellers in a stable real-estate market produces an equilibrium outcome in which noisy residences tend to be occupied by people with a low willingness-to-pay for quietude (imperturbables) and quiet residences tend to be occupied by those with a high willingness-to-pay. A change in the noise environment such as construction of a new airport runway alters relative supplies of noisy and quiet residences and eventually leads to new market equilibrium. In practice, environmental conditions and market adjustments are more complex. Noise exposure varies with distance to sources and residents may be able to adjust to environmental changes by the so-called averting behavior, such as installation of soundproofing windows. Furthermore, relocation is not costless, and the initial response of residents may be to voice their concerns through political processes and protests rather than voting with their feet and exiting the noisy neighborhood. Differences in housing values and noise levels yield a noise discount that falls as distance from the source increases, but care is required by empirical researchers in order to obtain unbiased estimates. A variety of estimation issues and other special concerns exist.

Sound intensity for a single event is expressed in decibels (dB), which is measured on a logarithmic scale. Perceived loudness doubles for each 10 dB increase, which is a tenfold increase in sound intensity. Noise measurements for transportation sources rely primarily on cumulative noise energy exposure measured using the day-night average sound level (DNL) or similar exposure measures such as L_{den} . For traffic and railroad noise, it is also common to use measurements from the noise distribution such as the median sound level or L_{50} . Both approaches use an A-weighted decibel (dBA) to adjust for the human ear’s sensitivity to different noise frequencies. As a cumulative measure, DNL is the equivalent energy-averaged sound level in dBA during a 24-h period with a 10-dB penalty for nighttime noise. “Equivalent” means the acoustical energy of an average steady-state sound equals the energy from actual time-varying sounds. Early research by acousticians established a relationship known as the Schultz curve between noise exposure and percentage of the population classified as “highly annoyed.” The effective origin for the Schultz curve is not an ambient sound level of zero but some higher background value such as 55 DNL, which is the threshold used presently in the United States. At a given exposure level, aircraft noise is more annoying, followed by traffic noise and then rail. However, debate continues about which aspect of the noise distribution is most important for human annoyance with other duration and event measures suggested as appropriate, such as exposure time above a sound level of 65 dBA. Experimentation with different noise measures is a feature also of some property value studies. Formally, an HP estimating equation for the value of noise is derived in the following manner (Nelson, 1980):

$$V = b_0 Z^{b_1} A^{b_2} u_1 \quad (1)$$

where V is property value or rent; Z is a set of physical, locational, and neighborhood housing characteristics; A is subjective annoyance due to noise exposure; the b -terms are coefficients; and u is a stochastic error term or residual. Examples of housing

characteristics include square footage, proximity to employment, and school quality. Annoyance is expressed by a modified Schultz curve:

$$A = c_0 e^{c_1(DNL)} u_2 \quad (2)$$

where the c -terms are coefficients and e is the natural log base. Taking logs of Eq. (1) and substituting for $\ln(A)$ from Eq. (2) yields the following estimating equation:

$$\ln V = d_0 + d_1 \ln Z + d_2 DNL + u_3 \quad (3)$$

where the d -terms are reduced-form coefficients obtained after substitution. The coefficient $d_2(100)$ is the percentage change in a property value for a decibel change in noise exposure or the so-called noise depreciation index (NDI). Differentiating Eq. (3) with respect to DNL yields the marginal HP of noise equal to $d_2(V)$, which is increasing in V . An NDI of 1% implies a \$2,000 decrease per dB in the market value of a \$200,000 property, other things being equal, which is the present value of a future stream of costs. If the difference in noise exposure for quiet versus noisy neighborhoods is 10 dB, otherwise identical homes are priced at \$200,000 and \$180,000. At an annual real discount rate of 4% and 30-year lifetime, the annualized value per 10 dB is \$1157 per year. Debate exists regarding the constancy of NDI across noise levels and its transferability over time and space. Econometric regression techniques are used to ensure control of the large number of other features of residences that determine market values. Common estimation errors include ignoring ambient thresholds for human annoyance and using a log-transformation of noise exposure levels. There are several other issues that researchers deal with that are on the frontier of applied econometric research. First, Eq. (3) yields a marginal price, rather than an inverse demand or willingness-to-pay function. An important theoretical contribution by Rosen (1974) showed that a two-stage approach is necessary to estimate the latter function, but relatively few HP studies have estimated second-stage demand functions (Day et al., 2007; von Graevenitz, 2018). Potentially this is important if the area affected by a noise abatement project is large or noise sources are not localized. Second, estimation of HP equations may require accounting for housing submarkets if residents and residences are differentiated or segmented in some important manner such as private and public housing, resulting in nonuniform HPs. Unlike many consumer products, houses are durable, infrequently traded, and short-run supplies are relatively fixed for properties and characteristics. Use of GIS methods and large data sets often yield samples that cover substantial portions of an urban area, where submarkets are more likely to be encountered. Housing submarkets also are one possible way to identify second-stage demand functions as clusters of properties may occur along several important dimensions of housing, both structurally and locationally. Furthermore, HP functions for noise and other housing attributes may be nonlinear or estimated using binary dummy variables, which complicate identification of submarkets. More recent HP studies frequently employ spatial autoregression and autocorrelation methods to avoid inefficient coefficient estimates, which also correct for interdependence produced by submarkets (Allen et al., 2015; Cohen and Coughlin, 2008). If enough data are available, hedonic analysis can be conducted for properties sold both before and after an event or project, thereby creating what is closer to a natural experiment (Boes and Nuesch, 2011; Ossokina and Verweij, 2015; Palmquist, 1982).

Beyond concerns with econometric estimation, there are several related issues with important implications for application of HP results. Access to transportation or to transportation-related employment is likely to have positive effects on property values, which means empirical studies must attempt to isolate effects of noise from effects of accessibility. If noise and access were perfectly correlated, estimation problems might be easily resolved but usually this is not the case. Failure to account for accessibility will bias noise costs downward and might lead to incorrect noise policy conclusions. Fig. 1 illustrates the problem for an airport, where elongated contours reflect noise exposure and circles represent accessibility. Some sideline properties can have a high degree of access but experience low noise levels. New highways and railroad terminals also will heighten access for travelers and employees, but external costs can be incurred by a larger number of people. The policy dilemma is clear, as net beneficiaries cannot easily compensate those who are net losers.

A related issue is the ability of property markets to adjust to major changes in transportation networks. Informational asymmetry between sellers and buyers has the effect of underpricing of higher quality homes (lemons problem). However, major new facilities

Figure 1 Airport noise contours and accessibility rings. Source: Adapted and reproduced with permission from European Aviation Safety Agency, 2016. European aviation environmental report 2016. EASA, Cologne.

usually are announced far in advance of construction, so there often is ample time for property markets to adjust to forthcoming events. For example, homebuyers have a rough idea of future noise levels from airport master plans. Many airports also use noise hotlines or have a noise ombudsman. At Melbourne's Essendon Airport, operators of aircraft are required to sign a Fly Neighborly Agreement. Some municipalities require that prospective homebuyers are provided with a noise disclosure statement. A study by Pope (2008) of pre- and post-disclosure property sales near a major airport found that the NDI increased by 55% after a disclosure requirement was mandated. The study concluded that HP estimates may be substantially biased if real-estate buyers are poorly informed about housing attributes. In a spatially efficient housing market, the Law of One Price should hold subject to allowance for relocation costs (Waights, 2018). That is, given a period of adjustment, land prices compensate for differences in residential amenities and disamenities as individuals self-select among locations according to willingness-to-pay. A study of the Zurich airport found that it took 2 years for apartment rents to stabilize at new equilibrium values after major changes in aircraft flight paths (Almer et al., 2017). However, a study of dwellings in Maarssenbroek, the Netherlands, found no relationship between noise sensitivity of residents and noise exposure, suggesting inefficient sorting (Nijland et al., 2007). Additional research is required on this critical issue.

A strength of the HP method for valuation of noise is that people's willingness-to-pay for quietude is revealed by actual choices made in market settings. Monetary values also are top down and avoid a potential double-counting problem in benefit-cost analysis that arises when summing across multiple effects of a project. One weakness is that specification of Eq. (3) for housing attributes is complex, including numerous locational variables as well as structural features. Measurement issues can arise such as correlation of noise exposure with other pollutants or with safety concerns. It is unlikely that housing prices capture long-term health effects, but fewer residences now exist at levels above 65 DNL. Average NDI values for aircraft, road traffic, and railroad noise are summarized later after discussion of CV studies.

Contingent Valuation Studies of Transportation Noise

The main alternative to HP studies is a stated preference study that uses survey-based responses to hypothetical choices between more or less of an environmental amenity or disamenity. In the first instance, focus is on maximum willingness-to-pay for an amenity and, in the second, minimum willingness-to-accept compensation for exposure to a disamenity. These potentially different monetary measures of welfare reflect differences in implied property rights assigned to either the status quo or the proposed environmental change. Many economists regard this choice as an ethical issue for society. In stated preference surveys, hypothetical choices are contingent on differences in costs associated with a payment mechanism, such as local taxes, monthly rents, or costs of travel. Hence, stated preference values are often labeled CV estimates. Thousands of CV studies have been conducted for environmental, health, transportation, cultural, and other issues. For transportation noise, there are several hundred CV studies, but most are for the United Kingdom and Scandinavia and very few for North America and other areas. Advantages of CV studies are that cost estimates can be based on both perceived and objective measures of noise; differences in costs can be examined for individual characteristics (age, income, family size, etc.); hypothetical settings can be employed that are unobserved in HP studies; and nonuse valuation is possible. For example, a CV study of traffic noise in Lisbon found that annoyance continued below noise levels used as ambient background levels for HP studies (Arsenio et al., 2006). A CV study of the Dallas-Ft. Worth Airport in the United States found that at severe noise levels many individuals were unwilling to consider a residence close to the airport and hence their willingness-to-accept dropped to zero (Feitelson et al., 1996). These results illustrate possible dangers of averaging across noise-exposed populations in HP studies. On the other hand, CV surveys lack the sorting effects that are implicit in property markets, suggesting CV estimates may be biased upwards as a consequence. The disadvantages of survey-based CV methods are well known: choices are hypothetical and may be simplistic or unrealistic; inexperienced respondents may not have well-defined preferences; and a variety of biases may distort estimates including starting point bias, framing bias, scope insensitivity, interviewer bias, and strategic bias in the form of invalid large responses or zero responses (protest zeros). The last problem is frequently dealt with by trimming the sample of responses in some manner. Furthermore, noise trade-offs are fundamentally a spatial issue and survey methods may lack this important dimension. That is, the survey should remind respondents that there are both substitutes and complements for a given abatement option. These problems might be overcome by appropriate sampling of respondents and by careful construction of the survey instrument. Combining HP and CV estimates also is possible such as concurrent estimates for both methods for a given location or through use of benefit-transfer methods. Formally, CV surveys may be phrased in terms of willingness-to-pay for improvements or willingness-to-accept deterioration of the residential environment. Consider the following questions that compare the status quo with its alternative: would you be willing to pay \$X extra each month in rent to live in a quiet environment? Or how much extra rent per month would you be willing to pay for a 50% reduction in nearby traffic noise? Or which of the following cost-amenity choices do you prefer? Alternatively, willingness-to-accept questions include: if your taxes fell by \$X would you be willing to relocate to a noisy environment? Or how much compensation would you require if the traffic volume and noise increased by 50%? Or if you could save \$X in travel costs per month would you be willing to live closer to a busy highway? These are proxy measures of noise exposure, but advocates of CV estimates sometimes claim this is an advantage of survey-based methods. Some questions are open-ended, while others follow a bidding game format. In some cases, the CV survey takes the form of a binary or yes-no choice containing only a few attributes, but complexity of the experiment may require that noise is considered along with other amenities and disamenities. Sometimes this is done to avoid disclosing the real purpose of the survey and thereby reduce concerns for strategic bias associated with local public goods, but it can also lead to embedding bias where responses on noise may include values for other attributes. Surveys have been conducted by mail, telephone, and in-person. A typical CV survey includes three sections: a description

of the environmental change, a section asking for monetary valuation of the change, and a set of debriefing questions for socio-demographic information about respondents. Following fundamental work by Carson (2012) and others, it is common to divide CV experiments into several phases that also can be used to judge the quality of existing studies: (1) pretest the survey instrument for its plausibility and understandability using focus groups or pilot studies; (2) determine that the population to be sampled and manner of payment are relevant for the proposed project or fit the institutional setting; (3) determine that the sample size is sufficient and properly weighted; (4) consider possible self-selection biases as these respondents are more likely to provide extreme estimates; and (5) include debriefing questions about why respondents answered certain questions in the manner that they did. Historically, neoclassical economists expressed doubt regarding the ability of behavioral surveys to produce truthful responses to complex questions regarding willingness-to-pay for both privately tradeable commodities and public goods. Although some objections have been addressed in CV studies, the most pressing issue is careful design of survey questionnaires where most economists lack training. For transportation noise values, this is one area where a concerted training program might yield substantial benefits. Although there is little work in this area, CV studies are one possible way to value health effects of noise or other nonuse values for which there is a willingness-to-pay such as moral sentiments and broader concerns for the environment.

Hedonic Price and Contingent Valuation Estimates: Benefit Transfers

A general problem in transportation economics is the use of values estimated for a given time and location that are applied to a policy issue in a different setting. Rather than conducting an entirely new study, investigators instead desire to use existing values by engaging in a benefit transfer (Nellthorp et al., 2007). Conducting a new primary study may be too costly, infeasible, or not readily available within allotted time. Benefit transfers thus use study results from one or more situations and extrapolate them to another similar situation. Economists have studied the circumstances under which a benefit transfer is possible and have constructed guidelines for doing so. A basic choice is between use of a single-value or point estimate and a function-based transfer. Use of function-based estimates has been shown to reduce transfer errors by a substantial margin (Kaul et al., 2013). Both types of transfers are aided by systematic literature reviews and meta-analyses. Systematic reviews attempt to answer a research question by collecting and summarizing all empirical evidence that meets a prespecified protocol for eligibility. Conducted in a critical manner, the results are useful for indicating strengths and weaknesses of each primary study, with a summary of evidence in the form of a range of values or average estimates. Attention is given also to the way the literature search is conducted with a focus on databases employed and keywords used in the search. Meta-analyses also are systematic reviews, but more advanced statistical procedures are used to summarize and analyze the primary study estimates. In the fixed-effect model, primary estimates are viewed as random draws from a common population of values and a weighted-mean is used to summarize the sample of estimates, with ideal weights defined by the inverse variance of each effect size. In the random-effects model, primary estimates are viewed as random draws from plural populations. Weighted-means again are employed, but ideal weights incorporate both the variance of each estimate and the between-effects variance due to sampling among multiple populations. Random effects thus allow for many unobserved factors that might underlie primary estimates and are preferred when heterogeneity is present but not easily explained. The best meta-analyses therefore obtain both a sample of similar effect sizes and the standard error or precision of each primary estimate. Meta-regressions can provide evidence on the extent to which estimates vary systematically according to both factual differences such as different countries or time periods and methodological differences such as different statistical methods employed in primary studies. Weighted-regressions again are appropriate. Table 1 displays estimates for costs of transportation noise from HP and CV studies obtained using systematic reviews, meta-analyses, and a few individual HP studies for rail noise.

The range of values is substantial, but this is not unexpected given the complexity of the problem. For average HP values, there is strong agreement across several reviews for each transport mode. For aircraft, there are over 50 primary HP studies dating back to 1967. The average NDI is about 0.70% per dB for aircraft noise with some suggestion of a slight increase since an early literature review in 1980. For road traffic, there are over 25 primary HP studies dating back to 1975. The average NDI is about 0.50% per dB for traffic noise with some suggestion of a slight increase since an early literature review in 1982. For rail noise, the number of HP studies is quite small and no systematic review exists. Studies for Berlin and Seoul indicate NDI values in the range 0.50%–0.65% per dB, which is not out of line with results for traffic noise. Results from CV studies also are summarized in Table 1, but these values are not directly comparable with HP estimates. Average CV estimates indicate a higher willingness-to-pay for abatement of aircraft noise compared to traffic and rail. For a smaller sample of estimates, the CV meta-analysis found that marginal values were much smaller below 55 dB and comparable for noise exposure in excess of that level. The analysis also concluded that use of decibel measures along with a description of annoyance yielded lower values than other survey approaches. In both HP and CV reviews, there are several attempts to examine variation across income levels. However, it has been demonstrated that the elasticity of income with respect to willingness-to-pay is not identical to conventional measures of income elasticity familiar to economists (Flores and Carson, 1997). This difference needs to be incorporated in future research on this issue.

Using Cost Values for Policy Questions

There are three major policy applications for cost values obtained from HP and CV studies. First, benefit–cost analyses of specific noise mitigation and abatement projects, including airport expansions, curfews and other quieting regulations, quieter aircraft and

motor vehicles, noise barriers, improved roads and highways, and abandonment or relocation of transportation facilities. Second, overall evaluations of full social costs of transportation, which are attempted to determine all paid and unpaid costs of each mode of transport. Third, evaluation of alternative policy instruments, such as calculation of noise and congestion taxes or user charges. Continued refinement of HP and CV estimates of noise damage costs will aid these policy applications. As one example, Becker and Lavee (2003) studied social costs and benefits of highway noise reductions in Israel. They conducted an HP study for a sample of 280 sales of occupant-owned apartments in three major Israeli cities, with noise exposure measured on a continuous basis for each dwelling in the sample. NDIs were 1.2% and 2.2% per dB for urban and higher-income suburban areas, respectively, which are at the high end of HP values reported in Table 1 for traffic noise. Net total benefit values were derived for two changes in noise standards: 67 dB–64 dB and 64 dB–59 dB contingent on abatement options for road restructuring, noise barriers, or apartment insulation. Overall results were mixed, with net benefits varying importantly with respect to location, density of housing, and nearness to roads. For example, apartment buildings as close as 25 m to a noisy road never passed a benefit–cost test for abatement. The authors suggested that a uniform national standard for traffic noise may not be optimal in economic terms but might be required on normative grounds.

Coming to the Nuisance: Is Transportation Noise a One-Time Cost?

People move or relocate for various reasons including a desire to avoid external costs of various disamenities, such as transportation-generated noise. Suppose a homeowner relocates to the vicinity of an environmental nuisance and then sues the generator of external costs for damages (a classic example is building a home close to an existing pig farm). In tort law, this is known as “coming to the nuisance.” In a simple two-person case, the parties might negotiate to arrive at an economically efficient solution provided property (ownership) rights are clearly defined and enforceable. As pointed out by Coase (1960), an efficient solution may not occur if property rights are not clearly defined or transaction costs are high, which is surely the case in most environmental problems involving transportation noise. However, as previously discussed, noise costs are capitalized into property values and reflected also in lower apartment rents, which compensates movers for newly incurred costs when they locate close to a highway or airport. Is

transportation noise therefore a one-time cost that society might choose to ignore or downplay as a continuing cost? Is it efficient to focus on the first mover's use of a resource and assign complete property rights to that user? An extension of Coase's theorem indicates that an economic analysis is incomplete unless the following thought experiment is conducted (Cordato, 1998; Wittman, 1980): who should have been first given current values for alternative uses of a resource? What is the highest and best use of the resource today? Which use of land resources will maximize economic efficiency, either homeowners or the airport? Answers to these questions require benefit–cost calculations, but Coase's analysis is complicated by focus on complete allocation of resources over time for both homeowners and the airport, including costs of relocation, abatement options, and other alternative land uses. Estimates also must be discounted to present values. Some observers argue that the experiment requires a level of knowledge that is beyond capabilities of courts and governments since the information required is a moving target, that is, the ideal efficient outcome may not be obtainable due to real-world costs of analysis. Another objection is that the first-party's right to use a resource is rendered less certain, which reduces incentives for efficient resource use and investment. A first-mover rule does send a powerful signal to other parties that their choices should be made with extreme care, thereby lessening conflicting land uses and moral hazard problems. However, it is frequently argued that external costs such as noise tend to be regressive and fall more often on poorer, minority, or disadvantaged groups in society (Chakraborty, 2006; Sobotta et al., 2007). These distinctive groups may therefore object to proposed changes on equity or moral grounds, raising ethical issues regarding legal standing and environmental justice. Suppose the proposed project is a new highway that impacts an existing older neighborhood. If the homeowners have a legitimate right to an undisturbed neighborhood, then the relevant measure of potential damages is the amount of compensation required if the proposed change did occur, that is, their compensating variation in income or willingness-to-accept. A willingness-to-accept measure implicitly assigns ownership rights to the homeowners and asks how much they require to sell their rights. The measure of gain to potential users of the highway is their willingness-to-pay for construction at the proposed location. Alternatively, if rights are assigned to potential users of the highway, measurements are reversed and for homeowners the issue is their equivalent variation in income or willingness-to-pay to prevent construction. These comparisons show the close connection between the measurement of noise values for public policy decisions and the costs and benefits of noise exposure, which is in part a distributional issue. In either case, a benefit–cost analysis is required but the outcome of the analysis may depend on assignment of property rights to amenities and disamenities from transportation.

Biography

Jon P. Nelson is Professor Emeritus of Economics at the Pennsylvania State University, University Park, PA. His research focuses on issues of public policy including transportation regulation, environmental economics, antitrust and utility regulation, and public health. He is the author of 3 books and more than 100 peer-reviewed articles and book chapters.

Introduction

Individuals as well as governments make decisions that reveal that they are prepared to forgo something else to reduce the risk of dying or being injured in traffic accidents. For instance, individuals may reduce their speed when driving with the purpose of reducing the risk of being involved in an accident, thereby increasing the time traveled, which is time lost for other activities. Governments may on their part decide to invest in safety measures that will reduce the risk of pedestrians at railway crossings, thereby reducing the amount of resources available for, for example, education. If individuals are well informed when they make their decisions, and their actions have no negative impact on others, then their actions will increase social welfare; they will only undertake actions that make them better off. Government actions are motivated by market failures, such as externalities, public good/bad, asymmetric information, etc., and since the government acts on behalf of the society its actions need to be evaluated.

We are in this chapter interested in traffic safety, but the models and methods discussed are applicable for other types of risks as well. There exist several approaches to evaluate safety measures. One approach would be to evaluate the measure based on the outcome in terms of less fatalities and injuries. That is, the measure with the largest reduction is the preferred measure. This of course ignores the cost of the measure and would risk prioritizing the most resource demanding ones, as it could be expected the more resources used the larger effects. An alternative approach that would take into account the costs would therefore be cost-effectiveness analysis (CEA). This approach would take into account the costs, relate them to the outcome, and provide an estimate of the cost per unit of output. One example would be the cost per life saved, that is, the cost of preventing one unidentified death in society. The CEA would result in a more efficient allocation of the resources since it would identify the more cost-effective safety measures or policies. However, CEA evaluates the technical efficiency of different measures/policies, but it does not take into account strength of preferences for the different policies, and cannot be used as a decision rule for resource allocation between sectors. This leads us to a third evaluation approach, which is the one usually favored by economists, that is, cost-benefit analysis (CBA).

CBA relies on both benefits and costs to be measures in a common metric, usually money. Since they are both measured in the same metric it allows for an analysis which provides information whether the policy is welfare improving for society. That is, if benefits exceed the costs, then the policy increases social welfare, if they do not then the policy will reduce social welfare. Since the foundation of CBA is based on welfare analysis, it is important that benefits and costs reflect their social value. For some of the benefits and the costs, it can be assumed that available market prices reflect their social value. However, for many other benefits and costs no market prices may exist. One example is the benefit of interest for this chapter, that is, traffic safety. As described earlier individuals value safety in the sense that they get a positive utility from being exposed to less risk (if we assume that they prefer to live compared to be dead, and prefer to be in good compared to bad health). However, there does not exist any easily available market price that reflects this value. Therefore in order for CBA to be able to take into account the benefits from reducing fatality and injury risks the value of safety needs to monetize. This monetization is done using the willingness to pay (WTP) approach. The aim of this chapter is to describe the theory behind this approach and some empirical methods used to obtain actual estimates.

The chapter is outline as follows. In the following section we describe the theory behind valuing safety by first providing a brief introduction before the main models. We then in the third section describe the main approaches and methods to elicit preferences for safety. The first part of that section focuses on methods using market data, whereas the second part focuses on methods that collect data using surveys. The chapter ends with a discussion and some suggestions for further reading.

Theory

Monetizing Safety Preferences

Before the WTP approach became widely accepted as the appropriate approach to monetize the value to society of reducing health risks the human capital (HC) approach dominated. Whereas the WTP is a preference-based approach the HC assumes that the value of an individual is reflected by his/her market productivity. For instance, if we illustrate the concept using the risk of fatality, the value of a life is estimated as the discounted expected future earnings, that is,

$$HC = \sum_{t=1}^T \frac{p_t y_t}{(1+r)^t}, \quad (1)$$

where p_t , y_t , and r are the survival probability conditional on surviving until t , the income in t , and the discount rate, respectively, and t and T define the time periods and end of life, respectively. The calculation is intuitive and straightforward, data necessary for the calculation are relatively easily available, and indeed estimates based on the HC approach are still used for policy purposes in some settings. However, its use for policy purposes is limited due to two major drawbacks: (1) nonmarket production is assigned a zero value, and (2) individual safety preferences do not enter the equation. The former suggests that unemployed and retired have a zero value. This seems both unethical and illogical, if society and its individuals also care for these groups, and it has been suggested to include also monetary values for nonmarket earnings, for example, services and goods produced in the household, and leisure time. This does not address, though, the main critique against the approach, that is, the second drawback. It has been shown that under some reasonable and plausible restrictions on the utility function the HC can serve as a lower bound of the value of a statistical life (VSL), which is a preference-based measure of the social value of preventing one statistical death in society, and hence in addition to not being a preference-based measure it will also underestimate the social value of safety. For these reasons it is out of favor among economists as the approach to elicit monetary safety values (unless for difficulty of getting necessary data to estimate preference-based measure the HC is the only approach available to obtain any monetary values).

We therefore focus on preference-based monetary safety measures in the reminder of this chapter. The concept and models described, as follows, can be used to monetize both fatality (mortality) and injury (morbidity) risks. Using fatality risk simplifies the presentation of the models, though, since it avoids the issues of severity and duration of injury - there is only one possible negative health outcome with fatality risk, that is, death - when describing the models. When describing the models, we will refer to the marginal WTP (MWTP) as the VSL. There is an ongoing discussion whether the best term for the monetary equivalent of preventing one statistical death is the VSL. Since the expression contains the word "life," it is sometimes misunderstood as measuring the value of saving an identified life. However, since VSL still is the main terminology used, we will also use it in this chapter. To stress that the VSL is not a monetary measure of saving an identified life the following example is illustrative:

Assume a region with a population of 100,000 in which six persons die each year in traffic accidents. The local government proposes a safety program that is expected to reduce the number of deaths in traffic accidents to 2 per year, that is, 4 fewer deaths per year. Suppose each individual in the region is willing to pay EUR120 annually for the proposed safety program to be implemented. This would mean that per statistical death prevented the population is willing to pay $\text{EUR}120 \times 100,000/4 = \text{EUR}3 \text{ million}$. That is, EUR12 million would be collected to save four lives, which would mean that the VSL is EUR3 million.

In the following two subsections, we first present the standard one-period model and then the multiperiod model for VSL. In each subsection, we also provide some of the main predictions of the models.

One-Period Model

Under the assumption that the individual marginal rate of substitution (MRS) and the personal risk change are uncorrelated, the VSL is the population mean of the MRS between fatality risk and wealth. The theoretical framework is a state-dependent utility model in which individuals are assumed to maximize their utility (Jones-Lee, 1974). Let p and w define the survival probability and wealth, and $u_s(w)$ the state-dependent utilities, where the subscript s defines staying alive ($s = a$) or dead ($s = d$). Individuals are then assumed to maximize,

$$EU(w, p) = pu_a(w) + (1 - p)u_d(w). \quad (2)$$

Utility functions are twice differentiable, and following the standard assumptions utility of wealth is higher if alive than dead, marginal utility of wealth is higher if alive than dead and nonnegative, and regarding financial risk individuals are weakly risk averse, that is,

$$u_a(w) > u_d(w), u'_a(w) > u'_d(w) \geq 0 \text{ and } u''_s(w) \leq 0. \quad (3)$$

Thus both the utility and the marginal utility are higher if alive than dead at any wealth level. Under these assumptions, the indifference curves over wealth and survival probability are decreasing and strictly convex. This is illustrated in Fig. 1.

Figure 1 The value of a statistical life. Source: Lectures notes, Henrik Andersson, Toulouse School of Economics, inspired by lectures notes by James Hammitt, Harvard University.

The compensating and equivalent surplus, that is, the WTP and willingness to accept (WTA), for a change in the fatality risk $\Delta p \equiv \varepsilon$ can be derived using Eq. (2). Let Eq. (2) defines EU_0 and let the WTP for the risk reduction ε be denote by $C(\varepsilon)$, then $C(\varepsilon)$ is given by,

$$(p + \varepsilon)u_a[w - C(\varepsilon)] + (1 - p - \varepsilon)u_d[w - C(\varepsilon)] = EU_0. \quad (4)$$

The WTA for the risk increase ε can similarly be denoted by $P(\varepsilon)$, that is,

$$(p - \varepsilon)u_a[w + P(\varepsilon)] + (1 - p + \varepsilon)u_d[w + P(\varepsilon)] = EU_0. \quad (5)$$

From Eqs. (4) and (5), it is evident that the WTP and WTA will depend on the size of ε , with both increasing with the change in the risk. However, it is important to stress that since the size of ε will be small in empirical applications, we expect WTP and WTA to be close to equal and that they are near proportional to ε .

As explained, VSL is the MRS between wealth and mortality risk, and it can be obtained by taking the limit of WTP or WTA when $\varepsilon \cong 0$, and is defined as follows:

$$VSL = -\frac{dw}{dp} \Big|_{EU \text{ constant}} = \frac{u_a(w) - u_d(w)}{pu'_a(w) + (1-p)u'_d(w)}. \quad (6)$$

It is obtained by totally differentiating Eq. (2) and keeping utility constant. The numerator contains the utility difference and the denominator the expected marginal utility. The assumptions in Eq. (3) ensure that VSL is always strictly positive.

It not possible to always in empirical applications estimate WTP and WTA for a marginal change in risk. For instance, in surveys it is necessary to ask respondents about a small but finite risk reduction. VSL is then given by the ratio between the change in wealth, for example, WTP, and the change in risk, that is,

$$VSL = \frac{WTP}{\Delta p}. \quad (7)$$

As explained, WTP is near proportional to the size of Δp . Eq. (7) should therefore be interpreted as an approximation of the VSL.

Selected Predictions from the One-Period Model

The theoretical model plays an important role in examining the validity of the preference estimates in empirical studies eliciting WTP and WTA for risk reductions. In addition to the prediction of near-proportionality described earlier, the two main predictions are that VSL increases with wealth and decreases with baseline survival probability. That wealthier individuals are willing to pay more is intuitive and in Eq. (6) is driven by the numerator that increases with wealth and the denominator that is nonincreasing with wealth, as a result of the assumptions in Eq. (3). Regarding the effect from the baseline survival probability, it is sometimes referred to as the dead-anyway effect, intuition being that if at a high risk why not spend the wealth on reducing the risk, and is in Eq. (6) driven by only the denominator and a result of the assumption that $u'_a > u'_d$.

The theoretical framework earlier has been extended to examine how background risks, that is, independent or additive risks to the specific risk of interest, compared to an overall risk as presented earlier, health status, financial risk, or ambiguity aversion influence the VSL. These predictions are also important for empirical applications, but the ones described earlier are the main ones, and for brevity of this description of how to value safety, we refer to the further readings for the discussion of these other predictions (Andersson et al., 2019).

Multiperiod Model

The single-period model described earlier can be extended to a multiperiod model in which the individual is assumed to maximize the expected life-time utility given by,

$$EU_\tau = \sum_{t=\tau}^{\infty} q_{\tau,t} (1+i)^{\tau-t} u(c_t), \quad (8)$$

where τ , $u(c_t)$, i , and $q_{\tau,t} = p_\tau \dots p_{t-1}$ denote the point of reference, the utility of consumption at time t , the utility discount rate, and the probability at τ of surviving to t , respectively. The extension to a multiperiod model is of high relevance in health valuation since it allows for an examination of how latency, that is, a delay of the health effects from being exposed to a risk (e.g. air pollution) affects individuals' WTP to reduce the risk. When eliciting preferences for traffic safety, it is usually assumed that the effect is immediate, that is, there is no time delay between the exposure to the risk and the health outcome. That is, the negative effect from being involved in a car crash is immediate and an action taken to reduce the risk of the crash will be an immediate reduction in the probability of death (or injury). Therefore latency despite its relevance in health valuation in general is not of great interest in valuation of traffic safety.

The multiperiod models are still of high relevance since it also allows for the examination of how age may affect the WTP to reduce traffic risk. Intuition would suggest that WTP to reduce fatality risk declines with age, since an older individual (*ceteris paribus*) has less to gain from reducing his/her risk. Both theoretical and empirical research studies have shown that this is not necessarily true, though. Regarding the theoretical predictions, it has been shown that the relationship between age and WTP will depend on the individual's optimal consumption path over his/her life and this path will depend on the assumptions of the model. Hence, the relationship can be considered ambiguous.

The discussion earlier concerns a temporary risk reduction that lasts one time period, for example, a risk reduction for one year at the age of 50. However, a risk reduction may last over several time periods, or be permanent. Any time period, though, can be treated as a series of shorter time periods, for example, the annual risk reduction can be treated as a series of monthly risk reductions. This means that the WTP for the longer time period can be calculated as the sum of the WTP for the shorter time periods that make up the longer ones. The multiperiod model has been used to examine the effect from treating WTP as a sum of a series of WTP compared to a one-period WTP. This question is highly relevant, since empirical studies have, as a mean to make the risk reduction larger, used scenarios with longer time periods. The theoretical findings based on the multiperiod model showed that precaution should be taken since with too long time periods and a high discount rate, the difference between a one-period and a series of time-periods models can be nonnegligible (Andersson et al., 2013).

Empirical Methods

The two approaches to monetize traffic safety preferences are broadly defined as revealed preference (RP) or stated preference (SP) methods, where the former employ actual market decisions and the latter decisions in hypothetical scenarios (Freeman et al., 2014). The actual techniques used in either RP or SP studies are usually referred to as nonmarket valuation techniques, since they monetize preferences in cases, like traffic safety, where easily available market prices are nonexistent. In the following sections, we will briefly describe some of the main approaches used to monetize traffic safety preferences.

Revealed Preference Methods

Discrete choices are one example of observed behavior. These includes, for example, whether to buy and/or use a bicycle helmet, use the seat belt, and use a reflector. Individuals will buy and/or use the safety equipment only if the benefits exceed the cost. Regarding those not using the equipment available, for example a bicycle helmet, their behavior does not suggest that they

do not have preferences for safety, only that the cost of buying and the disutility of using it are higher than the benefit of the risk reduction. Eq. (7) can be rearranged to show the necessary relationship between the benefit and the cost in a discrete choice situation,

$$WTP < VSL \cdot \Delta p. \quad (9)$$

The nature of the discrete choice therefore means that the estimates obtained from individual decisions among those using the safety device reflect a lower bound of their WTP. However, it may not be a lower bound of the population's WTP since among those who decide not to use the safety device the WTP is lower than the cost of using it. Hence, it is necessary to also take into account the part of the population not using the device when estimating the value to be used for policy purposes.

Data from discrete safety choices are informative for policy purposes. The relatively simple choice situations, the facts that choices are real, and that many choices are made on more than one occasion (i.e. respondents are familiar with the good) provide strong arguments for the use of this kind of data. However, caution should be taken. One important distinction to consider is the difference between expenditure and costs. For instance, a bicycle helmet can be used over a longer time period, which means that the analyst needs to be informed about the length of life of a bicycle helmet, which is not the expected length by the producer but the expected length of usage by the buyers. Other issues of concern are whether consumers indeed make well-informed decisions, any disutility of usage (which then is a cost), and how well informed the analyst is about not only the buyer's cost for and perceived risk reduction from the device but also the intended actual usage when the decision was taken.

Another example of an RP approach is the hedonic regression technique (Rosen, 1974). This technique investigates the relationship between the price of a good and its attributes. Let P and $Q = (q_1, q_2, \dots, q_k)$ be the price of the good and its vector of attributes, then the hedonic price function can be written as follows:

$$P = P(Q). \quad (10)$$

For example, assume that Q is a car then Eq. (10) states that the price of the car depends on its attributes, such as speed, comfort, etc. The underlying theoretical model for the hedonic regression approach, which in a competitive market assumes utility maximizing individuals and profit maximizing firms, shows that the MWTP for an attribute, q_k equals the marginal price change in the market for the same attribute, that is,

$$MWTP_{q_k} = \frac{\partial P(Q)}{\partial q_k}. \quad (11)$$

As indicated by Eq. (11), the hedonic regression technique examines the effect on the price, changing the level of one of the attributes holding the other attributes constant. Hence, if the examined attribute is the safety attribute then the increase in the price from an increase in that attribute can be interpreted as a safety premium. If the attribute q_k is adequately defined as a safety attribute of the car that reduces the risk of fatality in the event of an accident then Eq. (11) can be interpreted as the VSL of Eq. (6).

Central to the regression analysis is the functional form of the price function. Theory only states that the function should not be linear, but apart from that it is something to be decided empirically. Common functional forms in the literature have been the semi-log or the log-linear forms, that is, both using the log of the dependent variable. To illustrate, using the semi log the price function could be specified as follows:

$$\ln P_i = +X_i'\beta + \gamma_1 s_i + \gamma_2 q_i + \varepsilon_i, \quad (12)$$

where P_i is the price of the car i , X_i is a vector of car attributes (in addition to the risk variables), s_i is the probability of a fatal car accident, q_i is the probability of a nonfatal car accident, and ε_i is an error term. Based on the specification of the price regression in Eq. (12), the VSL is given by:

$$VSL = -\gamma_1 P, \quad (13)$$

where the minus sign is included, since the regression in Eq. (12) is defined using risk and not safety, and hence the minus sign converts the result to a positive VSL.

Stated Preference Methods

In SP studies respondents face hypothetical choice situations and are asked to make a decision as if it was real (Johnston, et al., 2017). The main weakness with the SP approach is that choices are not real, that is, respondents do not face the consequences of their decisions. However, the approach also provides advantages compared to the RP approach such as a control of the choice situations, since designed by the analyst, and flexibility, that is, the hypothetical choice situation can be tailored to the questions the analyst wants an answer to.

There exists a large range of different SP methods. In the following two sections we will briefly describe the two main methods, the contingent valuation method (CVM) and discrete choice experiments (DCE).

The Contingent Valuation Method

In the CVM data are collected through surveys, where respondents are asked to answer questions online, face-to-face, in paper questionnaire, etc. It is standard to collect information about socioeconomics and demographics, for example, income, education, age, to examine how such characteristics may influence the WTP, which can be used to both examine the validity of answers and for policy purposes. The core of the survey is the risk scenario and the WTP questions. To obtain valid estimates of respondents' preferences, it is important that the risk scenario provides an accurate description of the risk itself and how the risk reduction will be provided, for example by a public safety measure or as a private safety device, and that the scenario is understandable to the respondents. It is well established that individuals have difficulties understanding risk changes, and hence it is important to make sure that they understand the scenarios and find the questions relevant to answer.

The respondents may be asked to state their maximum WTP for the risk reduction directly in what is usually referred to as the open-ended format. The preferred format, by most analysts, is the referendum format, though. In the referendum format, respondents are asked to either answer yes or no to a question, where the risk policy and the cost to them of implementing it are described, or are asked if they would pay a specified amount (bid) for the risk policy or safety device. One reason why the referendum format is preferred is that it more resembles both voting and market scenarios, another is that it under some circumstances is incentive compatible, that is, respondents have incentives to state their true preferences. Following is an example of a referendum-format question.

Assume that the national transport authority will invest in the road network that will reduce the number of fatalities in the road network. Would you be willing to pay EUR200 for a policy that would imply that four fewer persons will die next year as a result of road accidents?

Yes ☐ No ☐

In this example, the information obtained will reveal whether the respondents' WTP is at least, or below, EUR200 for the risk reduction. To obtain a more precise range of the respondents' WTP, a follow-up question where the bid is increased if the respondents accept the first bid and lowered if they decline it is often included.

Regarding the empirical analysis of data from open-ended CVM studies, it is straightforward to use standard regression techniques, where details of the risk scenario like the size of the risk reduction and information about individual characteristics are used as explanatory variables for the respondents' stated maximum WTP. The referendum format provides closed-ended data, which can be modeled, using a latent variable framework. Let X_i be a vector of individual characteristics and the latent (unobserved) WTP can be specified as follows:

$$WTP_i^* = \alpha + X_i' \beta + \varepsilon_i, \quad (14)$$

where ε_i is an error term. Assuming that ε_i be normally distributed with mean 0 and variance σ^2 , the probability that respondent i accepts a bid with value r_i is then given by,

$$P(WTP_i^* > r_i) = P(\alpha + X_i' \beta + \varepsilon_i > r_i) = P(\varepsilon_i > r_i - \alpha - X_i' \beta) = 1 - \Phi\left(\frac{r_i - \alpha - X_i' \beta}{\sigma}\right), \quad (15)$$

where Φ denotes the standard normal CDF. The α , β and σ parameters can be estimated by maximum likelihood. Empirical evidence suggests that model specifications may influence the estimated WTP, and hence extensive sensitivity analysis should be conducted. One option is also to analyze the data, using nonparametric methods such as the Turnbull estimator.

Discrete Choice Experiments

In DCE the respondents face hypothetical choice situations with two or more alternatives. They are asked to choose between these policies and are usually also provided the option to opt out, that is, choosing the status quo. Compared to the CVM policies in DCE usually contain more than only two attributes (in the earlier-mentioned CVM example, the two attributes were the risk reduction and its cost). To illustrate, we provide an example of a choice situation, often referred to as a choice set, in Fig. 2.

It is evident from Fig. 2 that DCE can be considered as an extended version of the referendum format CVM. That is, if respondents were only to choose between the current situation and Policy B, that is, Policy A is removed from the choice set, and if injury risk was assumed not to be affected by Policy B, that is, the attribute related to injury risk was also removed from the choice set, then the choice situation in Fig. 2 would be identical to the CVM scenario earlier. The choice situations in DCE will be more complex for the respondent, but by including more attributes and choice alternatives more information can be extracted from the respondents. For instance, in the example in Fig. 2, we would be able to investigate how individuals trade off fatality and injury risk reductions, and not only fatality risk and wealth as in the CVM example. Moreover, CVM seems to be plagued by starting-point and anchoring bias when attempting to ask respondent more than one WTP question. This may be a result of the simplicity of the question format, and usually therefore only one CVM question is asked in surveys (with often one or two follow-up questions to get a more precise range of the respondents' WTP as explained earlier). In DCE the complexity of the choice sets mitigate the risk of anchoring or strategic answering and usually respondents are asked a series of choice sets where attribute levels differ between choice sets. This again means that usually more information about respondents' preferences can be extracted from a DCE compared with a CVM with the same number of respondents.

Assume that the national transport authority will invest in the road network what will reduce the number of fatalities and severe injuries in the road network.		
	Policy A	Policy B
Number of fewer individuals who will die next year when the policy is implemented	2	4
Number of fewer individuals who will be severely injured next year when the policy is implemented	300	400
Your cost	EUR 100	EUR 200
Which option do you prefer ☐ Policy A ☐ Policy B ☐ None of the suggested policies (today's situation remains and no additional cost for you)		

Figure 2 Example DCE question.

One issue to deal with when implementing DCE is the design of the choice sets: the number of attributes, the levels of these attributes, choice alternatives, etc. There exists a rich literature on experimental design and also several software programs to aid with the design of the DCE. Regarding the empirical analysis data from DCE are typically analyzed using a random utility model framework. Based on the example in **Fig. 2**, the utility that respondent n derives from choosing alternative j in choice set t is given by,

$$U_{njt} = \beta_0 \text{sq}_{njt} + \beta_1 \text{die}_{njt} + \beta_2 \text{injury}_{njt} + \beta_3 \text{cost}_{njt} + \varepsilon_{njt}, \quad (16)$$

where die_{njt} , injury_{njt} , and cost_{njt} are the attributes of the choice set; sq_{njt} is a dummy variable for the status quo alternative; the β s are the coefficient to be estimated; and ε_{njt} is a random error term, which is assumed to be IID type I extreme value. As described earlier, the VSL is the MRS between wealth and a reduction in fatality risk and the estimation of VSL based on Eq. (16) is therefore:

$$-\frac{\partial U_{njt} / \partial \text{die}_{njt}}{\partial U_{njt} / \partial \text{cost}_{njt}} = -\frac{\beta_1}{\beta_3}. \quad (17)$$

The standard model to examine the probability that respondent n chooses alternative j in choice set t is the conditional logit (sometimes also referred to as the multinomial logit):

$$P_{njt} = \frac{\exp(\beta_0 \text{sq}_{njt} + \beta_1 \text{die}_{njt} + \beta_2 \text{injury}_{njt} + \beta_3 \text{cost}_{njt})}{\sum_j \exp(\beta_0 \text{sq}_{njt} + \beta_1 \text{die}_{njt} + \beta_2 \text{injury}_{njt} + \beta_3 \text{cost}_{njt})}, \quad (18)$$

which can be estimated using maximum likelihood.

Observed preference heterogeneity can be taken into account in the conditional logit by including, for example, interactions between the attributes of the choice sets and respondents' characteristics. However, typically not all characteristics related to preference heterogeneity are observed and models taking into account such unobserved heterogeneity, like the mixed logit and latent class models, are often used in DCE studies.

Discussion

This chapter has provided a brief introduction to the theory behind and the main empirical approaches of valuing traffic safety. Nonmonetary utility-based health measures, such as health-related quality of life and quality adjusted life years (QALYs) (Hammit, 2002), were not cover, and for brevity the models and methods were described using fatality risk. The methods and model described can also be used, though, to value injury risk.

The WTP approach adopts the concept that individuals are the best judges of their own welfare. That welfare analysis should be based on individuals' own preferences is standard in economics, and the adoption of using the WTP approach to value safety

(risk reductions) is therefore accepted as the appropriate way to monetize safety preferences. Moreover, since both individuals on a daily basis undertake activities where they tradeoff safety for other goods, and that there is a veil of ignorance who will benefit from any safety policies implemented by governments, valuing safety is not considered as unethical among economists. Despite this, many raise concern about the fact that safety (health) is given a monetary value, as it suggests that lives or injuries (illnesses) are valued per se. As this chapter has explained this is a misconception of what is being valued and hopefully the chapter has been able to clarify this.

While there is strong consensus that the WTP (and WTA) approach is the appropriate way to value safety, there is less consensus what the appropriate monetary value should be. Economists do agree that there is not a unique value of the VSL, or any equivalent for specific nonfatal risk reductions, since such values will depend on the population and the context for which the WTP is elicited. However, empirical evidence suggests that values for the same population and context often differ. Such differences may depend on the empirical approach or technique used, or the data on which the analysis were conducted. Therefore much of today's research focus of "The value of life and health" is on how to empirically elicit monetary values that can be considered valid and reliable estimates of individuals' preferences to be used for policy purposes. Thus work is still in progress but a lot of progress has been done in the last decades regarding the empirical methods and data availability.

Introduction

The time spent in a public transport journey is a key element in user's satisfaction and modal preferences. The perception of travel time varies depending on whether it is in-vehicle time (IVT) or out-of-vehicle time (OVT). In turn, the OVT has at least two components: access to and egress from the bus stop or platform station and waiting for the service to arrive. There may be an additional time when users need to transfer between different transit services (e.g., bus to bus, bus to underground, and so on).

The perception of each travel time component (as well as any opportunities to be productive while travelling) varies as these take place in different environments (on-street, at the stop or platform, inside the vehicle) evoking different feelings (e.g., being anxious while waiting) and requiring different levels of effort (e.g., physical activity when walking). In terms of utility, the various travel time components detract from users' utility. In this regard, OVT is consistently more onerous than IVT.

Another element that influences user's satisfaction and loyalty to public transport is how secure and safe passengers feel when using transit services. By security we refer to the perceived risk of being mugged or subject to crime while waiting at a bus stop or station, or when traveling in the vehicle. Safety, on the other hand, refers to the possibility of suffering an accident while using a public transport service.

The perceptions of safety and security vary wildly in the population. In the case of safety, it is necessary to distinguish too if people are considering a fatal accident, a serious one leading to serious injuries—including losing a limb or becoming paraplegic—or just a minor injury. We will not consider these issues here, but the interested reader is referred to [Rizzi and Ortúzar \(2006\)](#) for a good review of evidence in this sense. In the latter case, there is not much work in the area of public transport related security, but interesting work has been done in terms of feeling of security when walking in potentially dangerous neighbourhoods ([Iglesias et al., 2013](#)) and we will discuss some of it below.

Value of Walking and Waiting Times

The access/egress and walking times depend on the distance between, say, origin and bus stop, and the average speed of walking. The walking distance can be estimated by asking individuals the pathway used or by assuming that transit users walk the shortest path ([Burke and Brown, 2007](#)). Another possibility is to ask for the access or walking times directly, and from this estimate the walking distance using average walking speeds for the gender/age of the individual.

Transport planners' rule of thumb was for many years that the maximum distance for walking to a bus stop was 400 m ([O'Neill et al., 1992](#); [Zhao et al., 2003](#)) and 800 m for accessing rail or underground stations ([Kuby et al., 2004](#); [Schlossberg et al., 2007](#)). However, [El-Geneidy et al. \(2014\)](#) have provided recently evidence that the 85th percentile walking distance to a bus stop is around 524 m from home (and 1259 m for rail) and suggested the importance of the revising the rules of thumb for different modes. Furthermore, [Mulley et al. \(2018\)](#) have shown that these values may also depend on service characteristics, such as frequency or comfort.

The waiting time at stops is the time (min) elapsed from the moment a person reaches the stop or platform to the moment they board the service. When headways (time between two consecutive buses or trains from the same service) are perfectly regular and patrons arrive randomly at the stop or platform, the expected waiting time $E(wt)$ is obviously half the headway (h). If services are not perfectly regular, such that the standard deviation of the headway $[SD(h)]$ is greater than zero, then the expected waiting time increases according to the following formula ([Holroyd and Scraggs, 1966](#)):

$$E(wt) = \frac{1}{2}E(h)\{1 + [SD(h)/E(h)]^2\}, \quad (1)$$

where $E(h)$ is the headway's expected value. Note that if arrivals were exponentially distributed, implying $SD(h) = E(h)$, then $E(wt) = E(h)$, that is, twice the average waiting time of a perfectly regular service. Thus regularizing services definitively contributes to lowering waiting times, and this is why public transport agencies make great efforts to increase regularity.

Another element affecting waiting times is crowding. If a bus or train service arriving at a stop or platform is very crowded, many users will not be able to board the service and will have to wait for the next arrival. Even if a service is not fully crowded, there will be some users, not pressed for time, who will prefer to wait for the next (or the one after the next) service to make a more comfortable trip. If this is the case, average waiting times will increase as effective frequency from the passenger's standpoint becomes higher than scheduled frequency (Batarce et al., 2016).

Real information about headways contributes to reducing anxiety for those waiting at a stop or platform. In addition, real time information can help transit users to better plan in advance their trips. Lu et al. (2018) studied the impact of real-time information about bus arrivals, finding that the expected waiting times were shorter when the bus users checked the bus arrival information before departure.

Regarding the values of access/egress walking time and waiting time, these are usually expressed as multipliers of the value of IVT, as evidence suggest that such multipliers are rather stable when compared across studies in different cities/regions/countries, enhancing their transferability. This gives local transport planners the freedom to estimate monetary savings without getting involved in complex currency transformations.

A large-scale review of British evidence (Wardman, 2014) recommended point estimate multiplier values for walking and waiting time (over IVT) of 1.62 and 1.68; the same study reported a multiplier of 1.93 for both walking and waiting time from nonUK evidence. In Latin America, however, these values tend to be further apart; for example, the seminal study by Gaudry et al. (1989), using carefully measured individual time and cost data for two corridors in Santiago, Chile, found that the walking time and waiting time multipliers were 1.60 and 4.34, respectively, when using their preferred Box-Cox specification. Therefore, the issue is not crystal clear. A recent study by the OECD/ITF (2014) concluded that, notwithstanding the heterogeneity within the evidence, a premium should be attached to walking and waiting time relative to IVT. Historically this premium was normally thought to be a multiplier value of 2.0, but more up-to-date evidence suggests the 2.0 may be an upper bound rather than an average, at least in the case of walking.

However, it has to be borne in mind that these point estimate multipliers may hide a great deal of variation depending on trip purpose, mode, distance, level of crowding, demographic traits, and type of data [revealed versus stated preference (SP)]. Furthermore, as they are, effectively point estimates, their confidence intervals may be (and usually are) quite large (Armstrong et al., 2001; Sillano and Ortúzar, 2005).

Another point to highlight is that frequent users' perception of waiting time is less negative than that of non-frequent users (Dell'Olio et al., 2011). This is unfortunate, because if transport planners want to encourage car users to switch to public transport by, for example, offering higher frequencies and greater spatial coverage, they will need to invest heavily in conveying this information to these nonfrequent public transport users, in imaginative ways.

Notwithstanding, if one considers official practice in social cost-benefit analysis of transport appraisal, the results are more consistent. For example, in the United Kingdom—which is a leading country worldwide because of the many studies carried out on this subject and their excellent official documentation—the Department for Transport establishes multipliers of 2.0 for the valuation of both waiting and walking time relative to IVT (UKDfT, 2017). Across the ocean, the US Department of Transport guidance on the valuation of travel time savings when evaluating competitive funding applications also requires applying a multiplier of 2.0 for both waiting and walking time relative to IVT (USDOT, 2011). These recommendations tend to be followed by most countries worldwide.

Value of Transfer

In the last decade, a large number of studies have focused on the analysis of public transport connectivity. Public transport users try to get to and from a wide variety of destinations. To do so, transferring among different public transporter services is necessary. Therefore transfers are the key elements in any public transport system, as they usually require taking time, effort, and costs; also to many users making a transfer implies subjective cost over and above the latter. Thus the total penalty associated with a transfer may be composed of four components, well differentiated: the transfer walking time, the transfer waiting time, a pure transfer penalty (associated with, for example, the anxiety and risk of missing the connection), and the variation of the latter depending on the transfer environment.

Transfer walking time is defined as the time (min) elapsed from the moment a person alights a given mode to the moment they reach the stop or platform to wait for a subsequent mode. The transfer waiting time, in turn, is defined as the time (min) elapsed from the moment a person reaches the stop or platform of a second (or third) mode, to the moment they are able to board it. The pure transfer penalty is defined as the sheer inconvenience of having to change to another mode or vehicle to reach the final destination. Its valuation is independent of the time spent in making the transfer, but it is strongly dependent on the transfer environment, that is, the quality of the interchange facilities in general (dark and empty, versus lighted and with commerce), the level of crowding experienced, the possibility to get a seat in the next mode, security and safety, if the transfer movement is at the same level or not (i.e., with escalators or elevators), and so on. It has also been found that the pure transfer penalty is influenced by the mental effort required for the "activity disruption" (i.e., having to change vehicle) involved in this situation (Wardman, 2014; Cascajo et al., 2018).

Unfortunately, most studies are not clear in distinguishing among the first three components of the transfer penalty. Some studies consider a pure transfer penalty, whereas some others interact it with the walking and waiting times involved in the transfer itself, but without properly differentiating these from the waiting and walking times in the first leg of the trip. Regarding the first type of studies, [Wardman \(2001\)](#) reports a pure transfer penalty of around 18 min for the United Kingdom. This figure increases if transfer conditions are not at their best; a transfer at its best has to be at the same level, requiring minimum physical effort, safe and secure conditions, and with enough information for users to find their way easily.

[Liu et al. \(1997\)](#) estimated the “transfer penalty” using revealed and SP data, finding that it was higher for changing from car to rail (equivalent to 15 min) than transferring among two rail services (equivalent to only 5 min). In addition, [Currie \(2005\)](#) and [Iseki and Taylor \(2009\)](#) reported a wide range of penalty values by mode, confirming that the intermodal pure transfer penalties tend to be higher than the intramodal penalties. This was also confirmed by [Navarrete and Ortúzar \(2013\)](#), who examined pure transfer penalties in the Santiago integrated public transport system, for different cases: metro–metro, bus–metro, and metro–bus, finding that users had a five times higher preference for transferring between two underground lines, than from bus to metro, and almost 2.5 times more than transferring from metro to bus.

Other studies have explicitly considered the transfer environment, as well as the walking and waiting times, and its effect on the pure transfer penalty. For the London Underground, for example, [Guo and Wilson \(2011\)](#) found that the transfer experience was better if transfers took place at the same horizontal level than if they required a vertical connection. [Douglas and Jones \(2013\)](#) arrived at the same results using a SP survey answered by bus and railways users in Sydney. [Raveau et al. \(2014\)](#) also found that the cost of the pure penalty transfer increased with the level of physical effort, using revealed preference data from both the London Underground and the Santiago Metro. Finally, [Navarrete and Ortúzar \(2013\)](#) reported that transferring between different levels was perceived as less convenient if there were no escalators.

[Raveau et al. \(2014\)](#) also studied the level of comfort (i.e., possibility of getting a seat) and crowding (likelihood of not to being able to board the first train when reaching the stop or platform to connect). With regard to comfort, they found that the greater the likelihood of getting a seat, the less costly the transfer was perceived; with regard to crowding it was the opposite, two sensible results. Finally, [Ceder et al. \(2013\)](#) found that comfort and safety made for a lower pure transfer penalty.

Some studies considered the effect of characteristics such as trip purpose (mandatory or nonmandatory trips), gender, and age. A mandatory trip conveys a higher transfer penalty than a nonmandatory trip, and elder people perceived transfers more negatively than younger people ([Wardman and Hine, 2000](#)). Despite this finding, [García-Martínez et al. \(2018\)](#) found that crowding was more penalized by younger users when transferring. In this sense, [Navarrete and Ortúzar \(2013\)](#) found that young patrons placed a higher value on the availability of information when transferring. Finally, the cost of transferring appears to be greater for females than for males ([Wardman and Hine, 2000](#); [Raveau et al., 2014](#)); females also place a higher premium on safety when deciding which route to take when making a transfer ([Cascajo et al., 2018](#); [Chowdhury, 2019](#)).

In conclusion the transfer penalty is indeed influenced by different factors such as the type of transfer, trip characteristics, the transfer environment, and the demographics of the public transport user. If transport planners want to lure car users to using public transport services more often, they need to devote substantial resources to improve the connections within the public transport system ([Chowdhury and Ceder, 2013](#); [Cascajo et al., 2018](#)). Otherwise, not only car users will not be attracted to using these modes, but it could also happen that current public transport users become less satisfied and eventually prefer to switch to the private car.

Regarding social cost-benefit analysis of transport projects, there are no official guidelines in the United Kingdom not in the United States to consider a pure transfer penalty. Official guidelines just require that walking time and waiting in transfers be valued at the same values as walking and waiting in transit trips of just one leg. However, this practice is not recommended, as it was one of the key reasons behind the monumental failure of the initial implementation of the Transantiago system in Chile ([Muñoz et al., 2009](#)).

Value of Security

Security can be defined as the freedom from being threatened by other people ([Beecroft and Pangbourne, 2015](#)). Travelling by public transport requires interacting with people on the street and inside a public transport unit (i.e., bus or train). In these instances, transport users may be subject to crime. The lack of supervision in vehicles, platforms, stops, and corridors makes public transport users vulnerable to attacks. Poor lighting and lack of visibility, when walking to and from stops or platforms, also create an environment favourable to crime. [Loukaitou-Sideris \(1997\)](#) states that a great deal of criminality occurred at bus stops in the Los Angeles mid and south-central corridors. [Smith and Clarke \(2000\)](#) described a range of crimes that may take place in public transport.

[Masoumi and Fastenmeier \(2016\)](#) cited several studies reporting perception of insecurity as a factor affecting mode choice. [Crime Concern \(2004\)](#) reported the results of a survey where public transport patronage would increase significantly (i.e., 7% in females, 10% in men, and 13 % in young people) if people were happier about their personal security. If, in addition, people who fear travelling by public transport do not have access to a car, they could be severely affected in their social life and even displaced from the job market.

Another reason for self-restrictions on the use of public transport is fear of terrorist attacks: a survey of Australians showed that some respondents avoided public transport because it was considered unsafe in this sense ([Aly, 2012](#)). In particular, [Bennetts and Charles \(2016\)](#) wrote that . . .

"Where users of passenger transport might previously have valued levels of service, cost, on-time performance and convenience as the most important considerations for the infrastructure's operation, it is possible that, with the increased specter of terrorism and asymmetric warfare, users might increasingly see personal safety and security as one of the critical prerequisites in the management of passenger transport."

Despite the relevance of crime and, more recently, terrorism affecting transit users' perception and willingness to use public transport, very little research has been carried out about the willingness to pay for improving security of public transport users. Most valuation studies related with personal security refer to safety as the impact of crashes occurring to a vehicle or an individual. The valuation of safety has a long-standing tradition and constitutes a mature field of analysis both at from a theoretical and an empirical level. This is not the case at all with security in public transport.

A literature review of security valuation studies when walking in urban areas only reveals a handful of studies. For example, Sillano et al. (2006) examined the issue of how to improve urban street design to increase the perception of security while walking in poor neighborhoods in Santiago, Chile. To this end, they designed a SP survey where respondents had to choose between different street environments for walking. Iglesias et al. (2013), improved on this work by adding better imagery and including a payment mechanism that allowed to estimate willingness-to-pay values for urban street traits related with the perception of security, in poor neighborhoods. Their SP experiment was posed for daylight conditions as, otherwise, street lighting would be the major factor hiding any other attributes that could affect the perception of security when walking. They concluded that elements associated with two metavariables, "visual control" and "natural vigilance" (being able to see and to be seen) contributed significantly to a higher perception of security.

Also inspired by Sillano et al. (2006), Borjesson (2012) designed a SP survey to determine how different physical environments influenced the valuation of walking time when accessing public transport. She found that walking in closed environments—not being able to see nor to be seen, and not been able to escape if an unforeseen threat occurred—and in darkness, induced more disutility; also that disutility was higher for women than for men. Finally, Larrañaga et al. (2018) analyzed a set of factors that contribute to facilitate utilitarian walking by means of a "best-worst" survey, responded by a sample of residents of Porto Alegre, Brazil. Related to security, they found that increasing the presence of police officers in the streets contributed to encourage walking.

In conclusion, the valuation of security with regard to public transport is in its infancy and should become a timely topic for attracting research. It should not only focus on the valuation of crime prevention, but also on the valuation of preventing terrorist attacks.

Demand Analysis in Economics

Classical economic analysis separates demand from supply, each a conceptually distinct relationship between quantity and price; it then looks for equilibria that are consistent with both. In that simplified world, the “demand side” expresses the preferences of consumers or institutions that might purchase a good, usually in terms of the quantity purchased at any given price. This idea naturally generalizes to cases where the quantity demanded depends not only on price but on quality attributes, which may also be endogenously determined in the market. The “supply side” of the analysis must describe what suppliers (i.e., firms, government, perhaps individuals) are willing to provide, in terms of quantities and quality levels, at a given price. For example, firms might be posited to maximize profits by choosing a quantity and various quality attributes, given a price of the good, and their knowledge of consumers’ quality valuations.

A common example in transportation is a congested highway, on which travelers care about price, average travel time, and variability of travel time—a measure of “reliability” (Brownstone and Small, 2005). Another example is use of public transit. Travelers care about price, access time, expected waiting time for a vehicle to arrive, and in-vehicle travel time. A supplier, whether a government or private firm, might choose price and those aspects of quality under its control, letting ridership be determined in equilibrium. Or the supplier might target ridership, based perhaps on the capacity of a subway tunnel, and use its knowledge of the demand side to optimize price and service frequency. Its objective might be profits, social welfare, or something else.

In both examples, the demand system reveals an implicit valuation of in-vehicle travel time, as well as valuations of waiting time or reliability. In practice, demand models reveal many valuations. For example, a model of choice of automobile might reveal valuations of size, power, and fuel efficiency. The fact that suppliers must know these valuations, perhaps in great detail, in order to design their services and products shows that the demand and supply sides cannot be as neatly separated as the armchair analyst might wish. Indeed, one of the major advances in analyzing public transit provision was to incorporate consumers’ values of waiting time into a cost function that a provider could then try to minimize (Mohring, 1972).

A classic “aggregate demand” model explains total use of a service, or total market for a product, for particular groups of consumers (e.g., those living in an urban neighborhood or those in a given demographic category). The model can be written as an equation expressing quantity x (e.g., daily passenger ridership or flow rate of automobile traffic) as some function of price and other quality attributes. If the functional form is linear in unknown parameters, and the price and quality attributes are summarized in a (column) vector z of “explanatory variables,” then we have the standard regression framework:

$$x = \alpha + \beta z + \varepsilon, \quad (1)$$

where α is a constant, β is a (row) vector of parameters, and ε is an “error term” denoting the inevitable imprecision in the model’s explanatory ability. The variables z might include price, in-vehicle time, and waiting time in the case of demand for public transit; or cost, average travel time, and variability of travel time in the case of a congested highway. They can also include nonlinear transformations or combinations of such quantities, as well as interactions between (e.g., products of) those variables and demographic characteristics; so the linearity of (1) is not very limiting. The unknown parameters α and β (the latter consisting of “coefficients” of each of the variables included in vector z) are typically determined through a statistical procedure to obtain the best fit to some data set on which the model is “estimated.” A common such procedure is “least squares,” which minimizes the sum of the squared deviations between actual and predicted values of x .

An example illustrates the relationship between a demand model and values of quality attributes. Suppose we estimate a linear regression model with three variables: price p , travel time T , and travel time multiplied by the individual’s wage rate w :

$$x = \alpha + \beta_p p + \beta_T T + \beta_{wT}(wT) + \varepsilon,$$

where β_p and β_T are expected to be negative since price and travel time are deterrents to use. Variable wT is included because in the most basic theories of travel-time valuation, time spent traveling reduces the time available for work. In this specification, travel time is implicitly valued at a rate:

$$VOT = [\beta_T + (\beta_{wT}w)]/\beta_p.$$

Formally, this “value of time” VOT is the marginal rate of substitution (within consumer demand) between travel time and price: you would give up VOT dollars in price in order to save 1 h in travel time, if the units of p and T are dollars and hours, respectively. Mathematically, it can be written as $(\partial x/\partial T)/(\partial x/\partial p)$. Empirically, it is often found to be approximately half the wage rate. In practice, studies of VOT use more elaborate specifications to account for other factors, such as work-hour constraints.

The variable “price” might include both the actual price and other quantifiable cost components, such as user-supplied fuel and operating costs of an automobile; the variable is then usually called “cost.” Furthermore, it may be convenient to incorporate some quality elements, appropriately valued, along with cost into a “generalized cost.” This works best when everyone has the same valuation. For example, if $\beta_{wT} = 0$ in the specification above, the generalized cost is

$$p_G \equiv p + (\beta_T/\beta_p)T,$$

which would replace the two variables p and T in the demand system. This simplification is often convenient when undertaking equilibrium calculations after estimating the demand model.

Naturally, most demand studies are more complex than this. An example is the demand for motorization, defined as per-capita motor vehicle ownership, across countries. Some researchers have posited a “partial adjustment” mechanism, in which actual motorization M_{it} in country i and year t adjusts from its previous year’s value toward a target value M_{it}^* :

$$M_{it} = M_{i,t-1} + (1 - a)(M_{it}^* - M_{i,t-1}) + \varepsilon_{it},$$

with the target value determined as a linear function of relevant variables such as per-capita income, population density, and urbanization. This specification implies a simple regression formula for M_{it} in which $M_{i,t-1}$ appears as an additional explanatory variable, with coefficient a . The estimated parameter a is a measure of inertia, and is positively related to the ratio of long-run to short-run responses to changes in conditions.

Discrete Choices

Many transportation decisions are made by choosing one of a set of discrete options. These choices are made by individuals (or other decision-making entities) who differ in observable characteristics of themselves or their environment, and also who differ in unobservable ways. A major change in demand analysis for transportation, beginning in the 1960s, was to develop rigorous models and statistical techniques to describe such behavior by individuals. These methods are called “discrete choice” or “disaggregate demand analysis.” A key innovation is to describe such choices probabilistically, thereby formally incorporating the unobservable determinants (McFadden, 1974, 1978). Aggregate forecasts can be made using a “forecasting sample,” of which each member can be assumed to represent a large population of decision-makers who are identical in their observable characteristics. A choice probability is calculated for each member of the forecasting sample, so aggregation amounts to assuming that this probability tells us the fraction of the subpopulation represented by this sample member who makes that choice.

The workhorse of discrete-choice analysis is the “additive random utility model” (RUM), in which a decision maker n chooses among alternatives j contained in a “choice set” $\{j = 1, \dots, J\}$, by selecting the alternative with the highest “conditional indirect utility” U_{jn} . (Note that one alternative may be not traveling.) This is one of many examples of deriving a demand function like Eq. (1) from a formal theory of utility maximization. In this case, utility is posited to have two additive components: a “systematic utility” V_{jn} that is a function of observable characteristics z , and a “random utility” ε_{jn} (also called an “error term”) expressing influences on the decisions that are unobservable to the analyst. In a linear-in-parameters specification, V_{jn} is a regression function linear in a coefficient vector, unlike (1) where it is quantity demanded that is a linear regression function:

$$U_{jn} \equiv V_{jn} + \varepsilon_{jn} = \alpha_j + \beta z_{jn} + \varepsilon_{jn}. \quad (2)$$

If K variables are included in vector z , there are $K + J - 1$ unknown coefficients: the K components of vector β , and all but one of the “alternative-specific constants” α_j . One of these constants (or any one combination of them) can be chosen arbitrarily in a “normalization” step because it is only utility differences across alternatives, not the absolute utility, that affect choice. (For the same reason, any portion of utility that is invariant across alternatives is excluded from V .)

The probabilistic aspect of choice arises because of the J random utilities $\{\varepsilon_{jn}\}$. By specifying a joint probability distribution for them, the analyst can calculate the probability of each choice once the coefficients are estimated and the observable characteristics measured. Often this distribution is assumed for simplicity to be identical for all decision makers n . Two probability distributions have been used extensively: multivariate normal and “generalized extreme value” (GEV). The former defines the “probit” model,

which has strong theoretical foundations, but the latter is more computationally tractable and thus far more widely used. The GEV cumulative distribution function is

$$F(\varepsilon_1, \dots, \varepsilon_J) = \exp[-G(e^{-\varepsilon_1}, \dots, e^{-\varepsilon_J})], \quad (3)$$

where G is a function increasing in all its arguments and satisfying certain other technical conditions, and $e \approx 2.718$ is the base of natural logarithms.

The most widely used GEV model is “multinomial logit,” sometimes called “conditional logit” or simply “logit,” in which function G is a simple sum. In that case, the random terms are independently and identically distributed (iid) with cumulative distribution function F equal to the product of J distribution functions, one for each alternative, each of the form:

$$\Pr[\varepsilon_{jn} < x] = \exp(-e^{-x}). \quad (4)$$

This univariate distribution is variously called “extreme value,” “double-exponential,” or “Gumbel.” Another common GEV model groups alternatives into “nests,” within which random terms are correlated but across which they are independent; that model is called “nested logit.”

The choice probabilities for the GEV model turn out to be rather simple in form. In what follows, we omit subscript n for simplicity. The probability of choosing alternative i is

$$P_i = \frac{e^{V_i} \cdot G_i(e^{V_1}, \dots, e^{V_J})}{G(e^{V_1}, \dots, e^{V_J})}, \quad (5)$$

where G_i denotes the i th partial derivative of function G . In the case of logit, this simplifies to

$$P_i = \frac{\exp(V_i)}{\sum_{j=1}^J \exp(V_j)}. \quad (6)$$

This probability formula has proven to be extraordinarily convenient both computationally and conceptually.

The conceptual convenience of (6) is that its denominator provides a summary of the value of the choice set to the decision maker, sometimes known as “inclusive value.” More formally, the log of the denominator is the maximum expected utility, that is, the expected value (in a probabilistic sense) of the utility achievable by a decision maker facing this particular choice set. This property of logit models permits them to be used as components of much more elaborate modeling systems. It also facilitates analysis of social welfare by, for example, calculating the benefits to any consumer segment of a specified change in one or more of the variables z . This same property extends to the GEV model, where the inclusive value is the denominator of Eq. (5).

Thanks to this property, it has become common practice in both academic and applied work to develop elaborate suites of models explaining many inter-connected decisions, linked together by these “inclusive values” within some specified nesting pattern. For example, the California High-Speed Rail Authority has forecast ridership of its planned new rail lines using models including trip generation by origin zone, trip attraction by destination zone, main mode (car, air, conventional train, or high-speed train), access modes at both origin and destination (for all the main modes except car), and route (including access station). The first two decisions are continuous choices, the others discrete. Typically, each choice occurring earlier in the above list depends on an inclusive value estimated for one or more of the later choices. However, all choices are viewed as simultaneous, not sequential, although they may incorporate time lags as in the partial-adjustment model described earlier.

The logit model has one serious limitation: the probabilities of any two alternatives have a ratio that is independent of characteristics of any other alternatives:

$$\frac{P_j}{P_k} = \exp(V_j - V_k). \quad (7)$$

This property is known as “independence from irrelevant alternatives” (IIA). It is unrealistic in many situations, which is why nested logit was first developed. The classic example is the “red bus—blue bus” problem, in which a transit agency operating a subway and a fleet of red buses adds a new choice, namely, a blue bus, that is identical to the red bus except for its color. Presumably, this addition would have little or no effect on subway ridership; yet Eq. (6) predicts that subway ridership would fall due to the expanded choice set (making the denominator larger). Nested logit alters this property by putting red and blue buses within a single nest, within which the error terms can be correlated. This allows blue buses to divert ridership preferentially from red buses rather than from subway.

Many other GEV models have been developed. We provide two examples in the next section. Many non-GEV models, still based on the random utility framework, have also been developed: for example, models using multiplicative errors, and models permitting alternatives to be complements as well as substitutes. In addition, researchers have specified models that jointly determine a discrete choice, such as what car to purchase, and an associated continuous choice, such as how much to drive that car.

Two breakthrough developments have greatly added to the usefulness of logit and other GEV models. First is “mixture models,” in which the coefficients themselves can be random (Walker and Ben-Akiva, 2011). The resulting probabilities follow, statistically, a mixture distribution that combines the assumed distribution of random coefficients (e.g., normal, log-normal, or triangular) with

the extreme-value distribution of the additive error term. The most common mixture model is “mixed logit,” in which probabilities are logit conditional on the values of the random parameters (McFadden and Train, 2000). This turns out to be very flexible, and frequently renders unnecessary the more complex mathematics of GEV or other more general models. Estimation of mixture models has become practical due to better computing power and the “method of simulated moments,” which approximates probabilities by simulating them numerically. Values for random coefficients are generated repeatedly from a process that follows their postulated joint probability distribution, choice probabilities are computed conditional on those coefficient values, and the results are averaged to approximate the true choice probabilities.

The second breakthrough is the use of “instrumental variables,” a well-known econometric technique long used to eliminate biases otherwise produced by endogeneity in explanatory variables. The prototype example endogeneity in discrete-choice analysis is the variable “price” for the study of automobile purchase. Price is often determined simultaneously with purchase choice because consumers care about quality attributes that are not measured by the analyst, but that affect the prices of vehicles being offered on the market. The innovation is to find one or more variables (instruments) that help explain the observed price but should have no direct effect on a consumer’s utility for a certain alternative—for example, a variable that summarizes the prices of other model cars offered by the same manufacturer. The instrumental variable can then be used to “purge” the variable in question (vehicle price) of its endogenous component.

Instrumental variables became popular for discrete-choice analysis when Berry et al. (1995) (often referred to as “BLP”) introduced them simultaneously with another important development: using a combination of disaggregate survey data and aggregate market-share information to estimate more efficiently a disaggregate choice model. This technique works because knowing the aggregate market shares permits an estimation algorithm to adjust for any tendency of its estimated coefficients to make forecast errors in those shares. Models that incorporate both instrumental variables and aggregate market-share data are now widely used in many branches of economics. At their core is the extreme-value distribution of a random utility term, as in Eq. (4).

Examples

In this section, we briefly review two empirical studies that used GEV models. The first is a study of potential demand for high-speed rail service in the Toronto-Montreal corridor (Koppelman and Wen, 2000). It was estimated on a sample of 2769 travelers who could choose among three modes: air, train, and car, denoted by $j = 1, 2$, and 3. (Bus was excluded because it had a very small market share, and bus-specific parameters could not be estimated reliably.) The results illustrate the flexibility of an intuitively specified GEV model to capture correlations among alternatives.

The model in question is the paired combinatorial logit model. It is based on the assumption that any pair of alternatives may show some degree of similarity in unobserved preferences. Similarity can be captured by allowing the random utility components of the alternatives to be correlated, and unlike with the nested logit model there is no need for pairs to be mutually exclusive. The generating function is a particular example of $G(\{y_j\})$ in Eq. (3):

$$G(y_1, y_2, y_3) = \sum_{j=1}^2 \sum_{k=j+1}^3 \left(y_j^{1/\rho_{jk}} + y_k^{1/\rho_{jk}} \right)^{\rho_{jk}}, \quad (8)$$

where it is required that $0 < \rho_{jk} \leq 1$ for each j and k . This model has three nests, consisting of all possible pairs of alternatives, each with its own “dissimilarity parameter” ρ_{ij} . From Eq. (5), the choice probabilities are:

$$P_i = \sum_{j \neq i} e^{V_i/\rho_{ij}} \frac{\left(e^{V_i/\rho_{ij}} + e^{V_j/\rho_{ij}} \right)^{\rho_{ij}-1}}{\sum_{j=1}^2 \sum_{k=j+1}^3 \left(e^{V_j/\rho_{jk}} + e^{V_k/\rho_{jk}} \right)^{\rho_{jk}}}.$$

Multinomial logit is the special case where $\rho_{ij} = 1$ for all three pairs i, j .

On the Toronto-Montreal data, the best-fitting model with dissimilarity parameters in the required range constrains ρ_{12} to equal one. Thus, only two dissimilarity parameters are estimated: one for the nest including air and car (ρ_{13} , estimated at 0.73), and one including train and car (ρ_{23} , estimated at 0.58). These results suggest that the travelers considered train and car to be the most similar modes, and air and train the least similar despite them being public modes that differ in access, privacy, and other characteristics from the car. One can only speculate as to why: perhaps access time at an airport is perceived differently or measured incorrectly, perhaps people especially strongly like or dislike flying, perhaps some people care especially about luggage capacity. (When the study was conducted, airport security procedures were not as stringent as they are now and are unlikely to have had a major influence on mode preferences.) The model statistically outperformed all other models tested, including multinomial logit and nested logit models. It also yielded significantly different own- and cross-price elasticities for the three modes. This illustrates that different models can produce substantially different demand forecasts for new travel modes.

The model estimation yields coefficients β_p , β_{IVT} , and β_{OVT} on variables indicating travel cost, in-vehicle time, and out-of-vehicle time, respectively. Their estimated ratios are measures of values of in- and out-of-vehicle times: $\beta_{IVT}/\beta_p = \text{C\$}19/\text{h}$ and $\beta_{OVT}/\beta_p = \text{C\$}80/\text{h}$, respectively (in 1989 Canadian dollars). The much higher estimate for out-of-vehicle time highlights the potential danger of considering only total trip time rather than accounting separately for the different stages of a trip.

The second example features the “ordered GEV” model. It is designed to handle situations where the alternatives are defined on an ordering along which one expects nearby alternatives to be most closely correlated. It was first used by Small (1987) to describe commuters’ choice of arrival time at work, taking into account that travel at the most convenient times might be slower due to congestion. The model was estimated using discrete (5-min) time intervals and a generating function with nests similar to those in Eq. (8), each containing two or more alternatives that form a sequence within the temporal ordering. A priori, arrival times that are close together (e.g., 8:00 and 8:05) are expected to be better substitutes than arrival times further apart (e.g., 8:00 and 8:30). Using the results, Small (1987) was able to estimate the disutility of arriving early or late for work, relative to the disutility of travel time. The trade-off between scheduling inconvenience and trip duration is central to the “bottleneck model” of trip-timing decisions and traffic congestion due to Vickrey (1969).

Data Sources

Discrete-choice models require extensive data to estimate. Values are needed for every characteristic of every alternative available to each individual in the sample. In particular, information is required on the characteristics of the transportation system including the costs, travel times, and reliability for every possible mode or route. Various shortcuts are possible. Nevertheless, for many practical investigations, these requirements are daunting. Consequently, models are sometimes broken up into parts, with entire teams of analysts and data-collection strategies developed for each part.

Values for the characteristics of the travel environment can be derived in several ways. Most often they are generated by some combination of observation and engineering calculation—for example as applied to a coded network describing all the roads and public-transport links in the study area. An advantage of such “objective” data is that they are not influenced by the limited knowledge, and perhaps biased perceptions, of travelers. (Although travelers’ perceptions may indeed affect their decisions, if perceptions are biased by the choices themselves, e.g., as a form of self-justification, they are unsuitable for predicting those choices.) A disadvantage of objective data is that they may not correspond to the quantities that actually influence travel decisions. For example, the point-to-point travel times on a coded network representing a public transit system may not accurately reflect the heuristics travelers use to choose a route, such as the distorted distances shown on a map of the transit system (Larcom et al., 2017), or the environment travelers may encounter at transfer points due to weather, noise, physical barriers, or lack of safety. Many models attempt to ameliorate such inaccuracies by including other variables, such as the number of transfers required for a journey and perhaps some observable characteristics of those transfers.

Another disadvantage of objective data on travel characteristics is that they may be highly correlated across the choice alternatives people face in real life, making it hard to separate the causal factors with satisfactory statistical precision.

Now let us consider the source of data on choices made. When data reflect actual choices in real-life situations, the analysis is termed one of “revealed preference” because individuals supposedly reveal the preferences that determine their choices. An alternative is for the analyst to design surveys in which respondents are presented with hypothetical choices. This is often called “stated preference” or “stated choice” analysis. It has the advantage that alternatives can be designed to minimize correlation and thus improve statistical precision. Stated preference analysis is also useful for forecasting potential demand for a new alternative that is unlike any that survey respondents have experienced. It has some disadvantages, however. First, people may not act in real life the way they say they would in a survey. A large research literature in survey design is aimed at finding survey techniques that minimize this problem. Second, if people misperceive a travel characteristic such as travel time, their response to actual changes may differ from what they think when the same changes are described hypothetically. This misperception can lead to errors in forecasting the effects of policies such as major transit investments or congestion tolls. Third, research has shown that people exhibit strong “loss aversion” to an unfavorable change in any particular characteristic relative to some subjective reference situation; this can affect stated-preference responses even though in real life individuals rarely are in a stable reference situation due to constant changes in their situations or in the travel environment.

Thus, both revealed preference and stated preference data have disadvantages. This difficulty can be partially overcome by using the two types of data together (Hensher et al., 1999).

Some analysts believe that only perceived values should be used to forecast behavior. But to make policy-relevant predictions, that approach must be supplemented with a model of perception formation so the analyst can predict how a given policy will affect perceptions, and in turn how it will affect actual behavior. Some progress has been made on this agenda, resulting in “attitudinal models” that incorporate both steps—often within a nested framework much like that described earlier.

One particular question of recent interest is whether cultural attitudes of newer generations toward driving may be causing a worldwide shift away from car ownership. There is some evidence of such shifts, but an unresolved debate about whether or not they can be explained by conventional explanatory variables such as home ownership, urbanization, income, fuel prices, and the changing characteristics of public transportation alternatives (Goodwin and Van Dender, 2013).

Activity Patterns

Travel is widely believed to be mostly a derived demand (i.e., not wanted for its own sake, but as a means to engage in desired activities distributed unevenly over time and space. A natural approach is to try to explain the underlying factors that motivate trips:

an idea that has led to “activity analysis” (Pinjari and Bhat, 2011). For example, one might consider work, shopping, errands, and entertainment as the desired activities, each with its own preferred frequency, time schedule, duration, and location. This type of analysis quickly becomes very complicated, as the number of potential combinations is enormous. Nevertheless, some practical models of activity choices have been developed and are now used by several urban planning agencies as the basis for forecasting travel behavior.

The advent of autonomous vehicles (AVs) is stimulating further research in activity analysis. Early evidence suggests that the availability of AVs will generate new trips for activities that were not previously considered practical, such as night travel by seniors who do not like to drive in the dark. AVs may also enable entirely new routing patterns since they can deliver people directly to destinations, and then park far away (Zakharenko, 2016). Preliminary analyses also suggest that AVs are likely to divert ridership from public transit, and so may exacerbate existing problems with traffic congestion and public-transit finance (Bahamonde-Birke et al., 2018).

Nonoptimizing Behavior

Most analysis of transportation demand, like most economic analyses of any kind, starts from an assumption that consumers are “rational” (i.e., that they choose optimally, in some definable sense, using a well-defined information set). This is a useful starting point for understanding human behavior, but few would accept it as a literal description. Indeed, psychologists and economists have observed numerous behavioral anomalies that suggest otherwise. The field of “behavioral economics” has begun to develop rigorous methods of accounting for many of them.

A few examples illustrate the possibilities for travel demand. First: studies tend to obtain larger estimates of the value of travel time when using revealed-preference rather than stated-preference data. One explanation is that people are prone to overestimating the time they lose due to congestion in practice.

A second example is the finding that survey respondents exhibit asymmetry to gains and losses when presented with alternatives differing in cost and travel time (De Borger and Fosgerau, 2008). In particular, they are more sensitive to losing cost or time (relative to some baseline) than to gaining the same amount of cost or time. Naturally, such so-called “loss aversion” could affect short-run responses to proposed or actual changes in the travel environment, and may be a factor in the tendency of people to oppose road pricing schemes before they are implemented but support them afterwards (Börjesson et al., 2012). For predicting long-run behavior, however, there is no obvious stable baseline for a population subject to continuous turnover in a continually evolving environment. Moreover, studies often find that loss aversion decays as people become familiar with gains and losses. Hence, asymmetry may be an important consideration for interpreting the results of stated-preference surveys, but not significant as far as affecting actual long-run behavior.

A final example is the alleged undervaluation of future fuel costs when choosing among automobiles (or other consumer durables) with different levels of energy efficiency. Much evidence, though not uncontested, suggests that such undervaluation is the norm (Gerarden et al., 2017). Several behavioral traits could account for it: lack of attention to fuel efficiency during purchase; inability to perform required optimization calculations; poor understanding of uncertainty in future fuel prices; purchasing a car for status rather than for its useful services; mistaken information about how fuel efficiency is correlated with other vehicle characteristics; lack of access to credit at competitive interest rates; and impulsiveness leading to decisions that are later regretted. There are some ways to empirically disentangle these possibilities, but such research is in its infancy.

More broadly, researchers have suggested that travel demand analysis needs to better formalize the decision-making process, with all its potentially “irrational” elements, and design data-collection and data-analysis strategies to measure all the aspects of decision-making. This is a big challenge, especially for a discipline that already has a reasonably good track record using “rational actor” models. Nevertheless, our understanding of travel behavior will be the better for measuring all the factors that affect it, whether “rational” or not.

Introduction

Congestion on transport infrastructures, whether road, rail, or other facilities, occurs when too many vehicles are trying to use an infrastructure, which has a fixed capacity in the short term. For instance, road users driving toward employment centers at the peak morning period, trucks or buses suffer from time losses they entail to each other. This result in delays when arriving at destination, losses of productivity for freight transport, and public transport buses locked in jams.

For a long time, economists have advocated the principle of road user charging whether for financing investments in capacity (Jules Dupuit in 1849) or taxing congestion to discourage excess travel when compared to fixed capacity in the short term (Arthur Pigou in 1920). Numerous research works have since developed these ideas and most transport economists today agree on a basic prescription: road user charging should be implemented, where and when congestion is critical, in order to ensure that potential road users consider the delay they impose on other road users when entering the road. By reducing traffic, this should entail gains in speed and in travel time reliability, a more efficient use of road capacity, and hence reduce the pressure to costly increases of this capacity. Speaking of road does not mean that congestion charging is restricted to this kind of infrastructure. Obviously this applies also to public transport users (rush hours fares), rail (path reservation), airports (take-off slot reservation), and so on. However, in the following, we concentrate on road congestion pricing schemes as these are the most difficult to implement.

The basic prescription is based on obvious simplifying assumptions and models. These are due to limits in analytical tools, in knowledge and ability to take account of the interactions of transport with the rest of the economy. This renders the design of optimal congestion pricing schemes particularly difficult. Nevertheless several “congestion pricing” schemes have been implemented around the world after decades of research and debates. Their current operative performance and some time elapsed allow us to assess their relevance through two basic questions: Are they effective in improving traffic conditions or Are they efficient, that is, improving the community welfare?

First practical guidelines and basic scheme parameters derived from theory of congestion pricing are set out. Then case studies of iconic successful experiences are described. Finally, an overview of successes and failures allow drawing some general lessons for implementation.

From Theory to Practical Guidelines

From theory of congestion pricing comes the prescription that where congestion is critical road tolls should be implemented and differentiated according to the variations of the marginal external cost of congestion that each road user imposes to each other. Given the road transport technology this marginal cost varies according to the heterogeneity of users (e.g., trucks vs. light vehicles) and road links (various peak-load technologies).

This implies that tolls should vary according to travel times (e.g., days in the week or time of day), travel place (e.g., link or area), vehicle type (e.g., car or truck) and trip purpose (e.g., commuting). This feature of pricing variation specifically distinguishes congestion pricing from flat road pricing whose main purpose is to finance infrastructure.

The basic expected benefits are improvement in traffic speed and hence time savings, which make the overall improvement in community welfare. Revenues raised from pricing are a transfer from road users to the community and do not count in the basic welfare evaluation. However, they may be earmarked for transport improvements or even redistributed to the concerned population and hence contribute to acceptability of congestion pricing.

Figure 1 Various geographies of road pricing schemes.

In practice, perfect toll differentiation cannot be attained because demand and cost elasticities knowledge is insufficient. However, some differentiation level has become recently feasible due to progress in (electronic) technology.

When it goes to practical implementation current real-world congestion pricing scheme can be characterized according to three basic parameters, which are its geography, operating hours, and rate structure.

Regarding the geography of a road pricing scheme three various forms can be distinguished (Fig. 1): one is the corridor pricing where users pay for traveling on the corridor road while parallel free routes may exist (e.g., Express Lanes in the United States); a second one is a cordon encompassing an area, generally a city center, where traffic crossing the cordon must pay a toll, whether inbound (e.g., in Oslo), outbound or both (e.g., in Stockholm); the third one is area pricing where traffic entering and driving inside the area must pay the toll (e.g., in London).

The second parameter is the operating hours. Toll can be enforced every day (e.g., Express Lanes) or only on weekdays at some times.

The third parameter is the toll rate structure. The rate may be flat (e.g., in London) or varying along times of travel (e.g., in Stockholm or Singapore).

Consequently behavioral alternatives may vary with various congestion pricing schemes. When facing corridor pricing the user can switch to another route. In contrast, when facing cordon or area pricing and if the destination cannot be changed like in commuting, road user cannot escape from paying a toll unless switching to another travel mode. For other trip purposes destination change can be an option. When facing time-varying pricing the user can reschedule his trip in order to save money. Finally, trip may be avoided when possible.

When it comes to technology, toll collection can use today wireless communications (dedicated short-range communications, DSRC) between a roadside beacon (e.g., a gantry acting like a control point) and the vehicle which passes it: vehicles must be fitted with an inboard unit (transponder) generally behind the windshield, with a properly inserted stored-value or credit card (e.g., in Singapore) or linked to a prepaid account (e.g., in California). Toll collection can also use automatic number plate recognition (ANPR) by cameras located at control points with various invoicing systems (e.g., in London).

One potential additional parameter is traveled distance or time-based pricing: this could be done today crudely by tracking vehicles when passing at various control points or in the near future, more accurately, with satellite technology tracking moving vehicles.

Case Studies of Ongoing Congestion Pricing Schemes

We first present three iconic schemes, starting with the oldest one, that is, in Singapore (1975), and then more recent ones in London and Stockholm in the years 2000. To these we add the “value pricing” schemes in the United States and then end by a brief summary of other schemes.

Singapore Electronic Road Pricing Scheme (ERP)

This is a multi cordon-pricing scheme in operation in its current form since 1998. Its objective is to manage traffic through road pricing so as to maintain free flow traffic on roads (Chin, 2010). It applies to all vehicles and operates on all days except on Sundays and holidays. It follows the 1975 mono-cordon paper-based and manually enforced pricing scheme targeting vehicles entering the central business district (CBD, 6 km²). There are now (in March 2019) more than 60 gantries (control points) disseminated on major roads or expressways of the island, in entry to the CBD and in crossing two cordons inside the CBD. ERP operates with DSRC. Charges and operation hours are different on the various gantries (they may operate from 5 h 30 min to 22 h 30 min except on Sundays and holidays). For instance gantries may charge a car from zero to 6 S\$ (3.9 €) depending on the hour of passing. During the day the rate may vary every 5 min, because of the fine-tuning according to the objective of congestion management. However, these rates are known in advance and revised every three months with the objective of maintaining a speed range of 20–30 km/h on arterial roads and 45–65 km/h on expressways. Gantries are also gradually added on different points including an outer cordon, based on the observed levels of congestion.

Singapore is an island-city of 716 km² with more than 5 million inhabitants and a GDP per capita just below that of United States. Land constraints, a high density and the objective of economic leadership are since the beginning the main drivers of its urban and transport policy. The 1975 “area licensing scheme” was operating initially only in the morning peak hour, in view of maintaining good traffic conditions in the CBD and hence attracting tourists, congresses and businessmen to foster investment. To this add a high level for vehicle annual tax (e.g., 650 € for a vehicle of 2 L engine capacity) and a restrictive policy for importing vehicles (Singapore has no automobile industry). Since 1990, quotas on importations are set by the Land Transport Authority (LTA) and the potential buyer of vehicle must bid for a “certificate of entitlement” (COE) for having the right to own a vehicle. For instance, in January 2019 the COE costs 33,000 S\$ (i.e., 21,500 €) for a vehicle of 2 L engine capacity. This package of measures concerning the buying, owning, and use of automobiles has succeeded with no doubt in maintaining traffic free flow even at peak hours. Moreover the government controls firmly land use, housing, and transport developments, making their matching effective and hence public transport efficient.

The government stresses that ERP is for traffic management and not for revenue raising. Thus the other vehicle taxes have been lowered in order to maintain revenue neutrality. The efficiency of ERP is evaluated with reference to observed travel speeds on roads. These two characteristics build the acceptability of the scheme. There is no explicit economic evaluation but the LTA manages to contain the ERP operation costs. Switching the ERP technology to a new satellite-based one is planned in 2020.

London Congestion Charging Scheme

The area-pricing scheme in London is in operation since February 2003 and applies to private cars and commercial vehicles (Leape, 2006; Santos and Fraser, 2006). Its objectives are to reduce congestion on roads, improve public transit by bus and the reliability of travel time, and make urban delivery freight and other urban services more efficient. Revenues are earmarked for spending in public transport. It was applied initially on an area of 22 km² encompassing the historic city and financial district. The area was extended further in 2007 but then came back to the initial one in 2011. The current charge of 11.50 £ (13.4 € in March 2019) is a day pass applicable for driving as much as one likes inside the area from Monday to Friday between 7 and 18 h except for bank holidays and celebrations. Enforcement is achieved through ANPR by cameras disseminated at entry points and inside the area. Payment can be made in advance by internet or various modes until midnight on the day of driving. Discounts are offered to those who pay on a monthly or annual basis. Vehicles exempted are two-wheels, taxis, vehicles for the disabled, vehicles for collective transport (at least nine seats), and low energy vehicles. Residents living inside the area can apply for a package of 4 £ for five consecutive days (i.e., a 90% discount). An emission surcharge of 10 £ (marketed as “T-charge”) targeting older vehicles added to the congestion charge and following the same operating rules and exemption policy was introduced in October 2017. This emission surcharge is to be replaced in April 2019 by the ultra low emission zone with tighter emission standards and operating on a 24/7 basis.

Great Britain has virtually no road tolls. The legislation authorizing the implementation of road or parking pricing schemes by local governments was introduced in 1999–2000. At this time, the transport conditions in London were recognized as especially bad, following decades of underinvestment. The discussion about congestion pricing started with the Smeed report in 1964 and has been since ongoing, sustained with numerous researches and modeling studies. This has resulted in a broad consensus in the opinion and decision makers on the necessity to “do something” to reduce automobile traffic. This period coincided with the first election of a mayor for the Greater London. Ken Livingstone, linked to the Labour Party, announced during the election campaign that he would implement congestion charging. He won the election in 2000, implemented the scheme and was reelected in 2004 after announcing in the new election campaign an increase of the charge and an extension of the charging area.

The project was initially fiercely opposed by the conservative party, automobilists, trade unions, and inhabitants of the target area. One of the decisive factors in acceptability was the discount for inhabitants of the charging area and the exemption of vehicles for disabled. The mayor conferred abundantly with stakeholders, using various media. The discussions influenced the main parameters of the scheme, that is, the level of the charge, the hours of operation, and the area delimitation. However, it was never question of submitting the decision to a referendum. According to polls, before the launching of the scheme the opinion was half-divided between supporters and opponents of the project.

The charging area represented 1.5% of the Greater London surface and 5.2% of its population in 2003, but 26% of the jobs. At this time in the morning peak hour, less than 15% of people were taking the car to enter the planned charging area. Expected positive effects became apparent right from the start of the scheme. Vehicular traffic in charging area even decreased beyond what was expected by modeling studies, a drop not compensated by the slight increase of traffic around the area. A higher punctuality of bus services was observed resulting in an increase in patronage and a decrease in operating costs. The unexpected success in lowering traffic resulted in a negative impact on expected revenues. There seemed to be no evident effect on the economy whether negative or positive. Most of economic studies conclude to a net economic benefit despite the higher expected costs of setting up and operating the scheme. However, 4 years later congestion has reverted to pre-charging level: this can be attributed to increased roadwork and reallocation of road capacity to the detriment of cars.

Stockholm Congestion Tax Scheme

The cordon-pricing scheme in Stockholm started with a seven months trial from January 2006 and then became permanent from August 2007 (Eliasson, 2009; Börjesson et al., 2012). Its objectives are to reduce congestion and improve the environment. The cordon encompasses the Stockholm city heart (35 km², about 280,000 inhabitants). Stockholm city extends on several islands linked by bridges, which make the control of traffic easier through 20 “control stations.” The scheme operates from Monday to

Friday between 0630 and 1830 except on bank holidays and in July. A payment is due at each crossing of a control point inbound and outbound depending on the time of crossing: as of 2019 the price varies between 11 SEK at off-peak hours and 35 SEK at peak hour morning or evening (3.3 € in March 2019). However the charge is capped to a maximum of 105 SEK per day. Enforcement is achieved through ANPR at the gates and an invoice is sent to the owner of the vehicle. Vehicles exempted are two-wheels and vehicles for collective transport. Until 2008 alternative fuel vehicles were also exempted (and this exemption has proven to be the most important incentive to “clean cars” sales apart from other national incentives). The charges are tax-deductible for commuters: this amount to 60% reduction of the charges. The initial cordon was extended in 2016 to include a bypass motorway and the charge raised by 75% at peak hour.

Road pricing was initially allowed in Sweden only for financing new infrastructure. After first unsuccessful discussions in the 1990s on an investment plan for funding roads in the Stockholm region which would have been abounded by cordon pricing revenues, the idea of introducing cordon pricing on a trial basis was set forth by the municipality in 2003, based on a political alliance of the Social-Democrats and Green party at the national level. The law was changed in 2004 to allow for congestion charging, legally a tax to be approved by the national parliament. Support to the project was in a minority right before the start of trial but went in a majority after. A referendum was held in the city of Stockholm after the end of the trial (on the same day of local and national elections) and resulted in a majority for keeping the charges, while other votes organized in cities around resulted in a majority of opponents. The new government (new majority of center-right) decided to go on with the congestion charging while earmarking the revenues for road investment within an integrated package, including improvement for public transit and complemented by national funding.

The expected objectives are met since there is a decrease in vehicular traffic and pollutants emissions. These effects were still lasting at the same level five years later. Support by inhabitants of the Stockholm County is still around 60% despite a moderate decrease, following the charge increase in 2016. No effects were found in the retail sector. Most of economic studies conclude to a net economic benefit despite the high investment and operating costs of the scheme.

Value-Pricing in the United States

“Value pricing” is the official name in the United States for the federal congestion pricing pilot program (DeCorla-Souza, 2004). This gives a positive connotation to congestion pricing, with the idea that by increasing flow and speed on tolled infrastructures, their users benefit from improved service quality and this increases the infrastructure value for the community. Currently, there are three kinds of implementation: granting access to a high occupancy vehicles lane (HOV) for solo drivers accepting to pay a toll, thus making it into a high occupancy toll lane (HOT); creating lanes adjacent to existing ones and tolling them in order to finance their building; implementing variable tolling on existing (flat) tolled facilities.

While being generally successful HOV lanes are often perceived as underutilized because of the speed they offer and making them into HOT lanes is a way to increase acceptability of reserved lanes. One of the first examples is that of Interstate 15 North-South in the San Diego region (California). Initially it was an 8 miles stretch of two reversible HOV lanes. The HOT scheme started at the end of 1996 and is in operation on a 24/7 basis. The rate is variable and responsive since it depends on actual traffic in the lanes. The objective is to maintain a free flow on the HOT lane. In March 2019, the charge varies from 50 cents to a maximum of \$8 (7 €). Rate at the time of driving is displayed on signs along the freeway before entry to the HOT lane, allowing the driver to choose it or not. The lane remains freely accessible for carpools, vanpools, transit, and zero emission vehicles. The I-15 capacity has since been extended (and is currently being extended) according to the following “express lanes” principle.

The (first) Express Lanes SR 91, East-West in the same region, are four new lanes (two in each direction) added to the existing highly congested SR91 linking the Riverside and Orange counties to Los Angeles. 280,000 vehicles are traveling between the two counties on this expressway each day. The first express lanes were opened in the end of 1995 and since extended to an 18 miles stretch in 2017. These new lanes are fully funded by the tolls. Tolls operate on a 24/7 basis and vary according to the time of travel, direction, and trip length with hourly tolls between \$3.55 and \$22.25 for traveling the entire stretch (in March 2019) with reduced rates on holidays. Peak hour rates are revised every 6 months with the objective to optimize traffic at free-flowing speeds. Vehicles with at least three occupants can use the express lanes at free or with a 50% discount depending on the time and direction.

As of 2012, there were 24 pricing schemes applying variable pricing on freeways (including HOT and express lanes), highways, bridges, and tunnels in the United States. Since HOV are allowed also on new-built tolled lanes, the distinction between “express lanes” (marketing name) and “hot lanes” (technical name) becomes blurred.

Other Ongoing Schemes

Other congestion pricing schemes are in operation in the world. Italy has a tradition of limited traffic zone (ZTL), restricting the access of vehicles to historical centers in several cities. Milan switched from its ZTL (an 8 km² area) to a cordon-pricing scheme named “Ecopass” in 2008, operating on weekdays (Beria, 2016). It was environmentally oriented through a pricing structure depending on emission standards of vehicles. Due to the growing share of traffic by clean vehicles exemption from payment, the scheme evolved in 2012 after a referendum to “Area C” with a flat rate during weekdays. Durham (United Kingdom) and Valletta (Malta) also operate restricted access through pricing to their historical center (area of less than 1 km²).

Major cities in Norway have implemented cordon tolls charging inbound traffic initially with the main objective of raising revenues to complement funding for road infrastructure and public transport (Ieromonachou et al., 2006). In Oslo, the scheme was launched in 1990, despite a public opinion predominantly against, operating on a 24/7 basis with a flat rate: it was low enough to

avoid social exclusion issues. In 2008, an outer toll ring was added and recently the rate structure changed, with a higher one in peak hours (morning and afternoon) on weekdays, paving the way to congestion charging.

Like in the United States, several tolled facilities in the world apply variable pricing by adding a markup at peak periods and sometimes reducing the toll at others (e.g., three tolled motorways in Paris region).

Overview

Despite these ongoing successes, few cities in the world have actually implemented congestion charging. The study of failures to do so is also instructive for candidate cities. In Lyon, a scheme combining a new urban tolled motorway with reduction in capacity of free parallel routes was cancelled in 1998 because of fierce public opposition a few months after its launching, leading to the reopening of free routes, buying back of the new infrastructure by the community and reductions of toll rates (Raux and Souche, 2004). Hong Kong failed to actually implement electronic road pricing, despite pilot test on the electronic road pricing system between 1983 and 1985, one issue being fear about invasion of privacy. Several near real implementation projects have been rejected because of fierce public opposition explicitly expressed through ex ante referenda like in Edinburgh (2005) or Manchester (2008). Numerous cities in the world are continuously debating about road or congestion pricing schemes since they are facing excess traffic on their roads and funding shortage for their transport system.

The first lesson that can be drawn from the ongoing schemes is that they are effective in improving traffic conditions: drivers are sensitive to cost, traffic flow is smoother and its harmful effects on the environment are reduced. Most of the appraisal studies also consider that these schemes are efficient, that is to say they improve the welfare of the community. However, this improvement appears on one hand lower than expected, given the unexpected high costs of setting up and operating the charging system. On the other hand, in cases of time-varying pricing the benefits may be underestimated given the possibility of rescheduling trips, a phenomenon which is difficult to introduce in conventional appraisal.

Successes and failures also indicate some basic conditions for a successful implementation. Regarding the political context this can be a strong political will backed by a lasting debate (as in London). This can also result from agreement between political parties backed by leveraging on national funding and a significant public support of environmental policies (as in Stockholm or Oslo). However, even if a political agreement is reached this does not exempt the local authority from taking high political and financial risks, as this was obviously the case with the seven months trial in Stockholm.

The success in Stockholm (and Milan) and the failure of some proposals elsewhere indicate that a referendum before any implementation is a sure way to get a rejection by the public. The study of opinion attitudes in the successful schemes shows that opinion is highly skeptical with a rising opposition until the scheme launching and then becomes quickly supportive after the scheme delivers smooth toll collection, operation, and benefits in traffic flow. The practical experience of congestion pricing reduces the legitimate fear about something which was previously unfamiliar.

Even if political acceptability can be reached through compromises between parties, public acceptability may be more difficult to achieve. Equity issues can be highly debated before the scheme acceptance. Research shows that there is no general diagnosis since it depends on the peculiarities of the scheme (where people live and work, which socioeconomic profiles will have to pay, etc.). Earmarking revenues and redistribution are seen as critical issues.

Congestion must be at a critical level to justify the setting up of a costly toll collection system. To alleviate congestion in other cases alternative policies are available, such as parking, regulating, pricing or developing bicycling, and carpooling along with transit (Arnott et al., 2005).

Introduction

Fuel taxes and congestion charges have repeatedly been shown to be highly effective policy instruments to reduce traffic emissions and road congestion, respectively. However, a recurring argument against them is that they are claimed to fall disproportionately on the poor. This chapter analyses this argument. For brevity, fuel taxes and congestion charges are referred to as “car use taxes.” Most of the discussion in the chapter is just as relevant for other kinds of car-related taxes, such as vehicle taxes, parking charges and vehicle sales taxes.

The purpose of a car use tax matters greatly for what conclusions are drawn. Many car use taxes, in particular when fuel taxes were first introduced, have been fiscally motivated: they are simply a convenient way to raise revenues for various public expenditures. In such situations, it is clear that the taxes’ distributional burden is relevant, and should be compared to other ways to raise public revenues, such as income, sales or property taxes. But more and more, car use taxes are seen as price corrections: they are motivated by a desire to make the cost of driving better reflect its total social cost, including externalities such as carbon emissions and road congestion. In other words, this kind of car use tax adjusts the price of driving to what it really should be; without it, driving is subsidized from a social point of view. From this perspective, it is much less clear in what sense distributional effects of car use taxes are relevant, and between which situations comparisons should be made. Prices are almost always the same for everyone, regardless of income or wealth, for two good reasons. First, it lets the individual decide for herself how to allocate her resources (money, time, etc.) between different goods and services. Second, it leads to an overall efficient allocation of resources across the economy through supply-and-demand mechanisms. Desires for increased income equity is instead usually handled by taxation and social welfare systems. Accepting a default position where prices are, generally, equal for everyone (with a few deliberated exceptions), it is natural to argue that the distributional effects of corrective taxes—taxes which are introduced to make the prices “right” in the sense that they reflect full social costs—are in fact essentially irrelevant. Indeed, allowing prices of car trips to be lower than their social cost (which they will be in the absence of car use taxes) effectively constitutes subsidies from society at large to car drivers, and these implicit subsidies accrue mostly to rich groups (Eliasson, 2016).

This being said, analyzing distributional effects may still be important, partly because most car use taxes have at least some fiscal motivation as well, and partly because any change in an existing price system causes transition costs when people adapt to the new prices.

Methodological Questions

When analyzing the distributional effects of tax instruments, several methodological questions need to be considered, most of which have no clear-cut answers.

Should Revenue Recycling be Included in the Analysis?

The first question is whether the recycling of the revenues should be part of the analysis. It is important to realize that the distributional profile of a revenue-generating tax instrument is one thing, and the distributional profile of an expenditure scheme is something else. They can be analyzed either separately, or together as a single policy.

One answer is that it depends on the decision context. If the revenues will be spent on something that will be carried out in any case, it is natural to compare the distributional profiles of different possible tax instruments in isolation, leaving the distributional profile of the planned expenditure out of the analysis. On the other hand, if one is considering introducing an earmarked tax for a specific project which will not be undertaken otherwise—say, a congestion charge necessary to fund an infrastructure investment—it may be natural to consider the distributional profile of the tax and the project together, as a single policy.

However, there is a strong argument for analyzing tax instruments and expenditure schemes separately, namely that the natural and conventional definitions of what constitutes “distributionally neutral” schemes are usually defined differently for taxes and for expenditures.

The most common definition of a distributionally neutral tax instrument is one which takes an equal share of everyone’s income. A tax instrument is defined as progressive if it takes a larger share of rich people’s income than of poor people’s; the opposite is called a regressive tax. This notion is formalized in the Suits index (Suits, 1977), defined as $S = 1 - 2 \int_0^1 T(y)dy$, where y is the cumulative share of total income and $T(y)$ is the cumulative share of the total tax burden.^a The index is bounded between -1 and 1 . A flat-rate tax has Suits index 0 , a regressive tax has a negative Suits index and a progressive tax a positive index.

For public expenditures, on the other hand, the most common^b definition of a distributionally neutral scheme is one which gives an equal absolute amount (or value) to everyone, a so-called lump sum distribution. An expenditure scheme is defined as progressive, if it gives a larger amount per capita to poor people than to rich people, and regressive, if it is the other way around. This notion is formalized in the concentration index (Kakwani, 1977), defined as $CI = 1 - 2 \int_0^1 s(x)dx$ where $s(x)$ is the share of total spending accruing to the poorest $x\%$ of the population. The concentration index is also bounded between -1 and 1 , just as the Suits index. If all citizens receive the same amount (lump sum spending), the index is zero. Progressive spending (more is spent per capita on low income groups) yields a negative concentration index, and vice versa.

Now, note that the definitions of distributional neutrality are different for taxes and expenditures: a neutral tax takes an equal share of everyone’s income, while a neutral spending scheme gives an equal absolute amount to everyone. This easily leads to paradoxical results when analyzing combinations of a tax and a revenue-recycling scheme as a single policy. For example, combining a neutral tax (a fixed share of everyone’s income) with a neutral expenditure scheme (a lump sum redistribution) turns out to be a progressive policy when seen as a combined policy, not a neutral one. It follows that it is easy to construct examples where a regressive tax combined with a regressive spending scheme is defined as a progressive policy when taken together and viewed as a single scheme, and vice versa: a progressive tax and a progressive spending scheme may be regressive when taken together. This is a strong argument for analyzing distributional effects of tax schemes and expenditure schemes separately, as this prevents this kind of confusion.

It is not uncommon that studies conclude that a car use tax is regressive, but together with lump sum revenue recycling the total effect is progressive. This mixes the two different definitions of “progressive”/“regressive” explained earlier, ending up in a conclusion that is completely trivial on a closer look. Taking an equal share of everyone’s income (a neutral tax) and handing the revenues back with a lump sum distribution (neutral spending) is of course a highly progressive policy combination to start with. That a tax instrument is not regressive enough to make the combination with a lump sum redistribution regressive is hardly surprising; if such a combination was regressive, the tax has to be extremely regressive in itself, effectively taking higher equal amounts in *absolute* terms from poor people than from rich people. Again, this shows that there are strong arguments for keeping distributional analyses of public revenue sources and public expenditures separate. In certain specific decision situations, however, it may still be natural to also consider a combined tax and spending scheme; the most common example is a car use tax earmarked for a project that will for certain not be undertaken otherwise.

Income or Expenditures as a Measure of Economic Status?

The second methodological question is how to define and measure individuals’ available economic resources. One way is to simply use disposable income, that is, the net sum of after-tax wages and transfers in a month or a year. However, this ignores that many people have other sources of money available to them. People may live off their savings or other sources of wealth, be supported by relatives (parents or a spouse), or have unregistered income sources. Moreover, some people may expect to have higher earnings in the future than they currently have, leading them to behave as if they borrow against their future income; this is especially relevant for students. Finally, income varies a lot between years, especially at the extremes. For example, someone selling a house or a company one year will have a very high income that particular year, but probably not nearly as high the next year. At the other extreme, some people may have extremely low incomes one particular year because they take a year off to study, take care of children or write a book, but in such cases their income are probably considerably higher other years. All this means that disposable income, in the usual sense, is not necessarily a full and fair measure of an individual’s economic situation.

A way around this is to use individuals’ expenditures as a proxy measure of their long-run available economic resources. An obvious drawback is that such studies must be based on the survey data rather than registry data, and registry data usually gives much bigger and more precise data sets. Studies suggest that using expenditures rather than disposable income as a measure of economic

^a In applications, data is usually given in discrete form for individuals or groups. Indexing these discrete observations by i , the Suits index is approximated by:

$$S = 1 - \sum_i (T(y_i) + T(y_{i-1})) (y_i - y_{i-1})$$

^b There are studies and contexts, however, where neutral spending is defined as a scheme where each individual gets an amount proportional to her income.

resources tends to make tax instrument look more neutral—progressive taxes become less progressive, and regressive taxes less regressive (Sterner, 2012).

Must Behavioral Adaptation be Taken Into Account?

A change in car use taxes will cause behavioral changes. This means that the welfare loss of a tax change will be accurately reflected neither by the total taxes paid after the change, nor by what would have been paid ignoring behavioral adaptation. The first alternative underestimates the welfare loss of a tax increase, as it ignores the loss in utility caused by adapting behavior, and conversely the second alternative overestimates the welfare loss as it ignores the possibility to adapting and hence partly avoiding the tax. It follows that only measuring the tax incidence, that is, how much tax different groups pay, may give misleading conclusions, as this neglects the welfare loss of behavioral adaptation.

Clearly, it is preferable to use a proper welfare measure—the Marshallian or ideally the Hicksian consumer surplus (see the chapter by Harald Minken in this volume)—rather than simply using taxes paid. However, this is not always possible, as it requires forecasting behavioral adaptations to the tax. Fortunately, the error induced by neglecting adaptation costs is usually relatively small. If a tax is increased by some fraction α and the cost elasticity of demand is ϵ , the relative error of the welfare loss if adaption is ignored is $\frac{\alpha\epsilon}{2}$. So, if a tax is increased by $\alpha = 10\%$ and the cost elasticity is $\epsilon = -0.5$, the relative error is 2.5%, which is negligible in most situations. Obviously, if the change is relatively large and demand elasticities are high and different across groups, the different between welfare loss and change in taxes paid may not be negligible anymore.

Must Second-Order Effects be Taken Into Account?

A change in car use taxes may change the prices of other goods and services as a second-order effect. This could mean that even individuals who do not travel by car are affected, as the prices of goods and services they consume may change. One case where this can matter is the price of public transport in poor countries, as diesel costs make up a substantial share of transit operating costs and poor groups make a much higher share of their trips by public transport than by car (Agostini and Jiménez, 2015; Blackman et al., 2010). This means that neglecting the second-order effect of a fuel tax increase on public transport prices, only considering the direct effect on driving costs, may underestimate the impact on poor groups.

Two Examples

Consumption taxes are usually slightly regressive, as high-income groups tend to spend a smaller share of their income on consumption, and more on savings. General sales taxes typically have Suits indices in the range -0.1 to -0.2 . Whether a consumption tax on a particular good is progressive or regressive depends on whether consumption of that good increases faster or slower than proportionally to income. In other words, a consumption tax will be regressive, if the consumption elasticity with respect to income is lower than 1, and vice versa.

Broadly speaking, studies suggest that the income elasticity of car use is slightly lower than 1 in rich countries and slightly higher than 1 in poor countries. This means that car use taxes tend to be mildly regressive in rich countries but mildly progressive in poor countries. Obviously, results will differ depending on the design of the tax, the context, what type of car use is taxed and so on.

To illustrate some fairly typical results and how distributional analyses can be carried out, two empirical case studies are presented below: a fuel tax increase and a congestion charge. While the specific results obviously pertain to these specific cases, the reasoning is general, and the general findings are fairly representative for most studies.

Example: Fuel Tax

The following case study shows results for approximately 10% increase of the Swedish fuel tax (reported in Eliasson et al., 2018). Distributional impacts are calculated as welfare losses relative to disposable income, where incomes are taken from the tax registry. Driving distances are taken from the vehicle registry, and vehicles' fuel consumption from vehicle type registrations. Welfare losses are calculated using demand elasticities estimated separately for different combinations of income quartile and type of residential area (large cities, small cities, and rural areas). Elasticities are medium-term, meaning that they consider changes in vehicle kilometers driven, but not changes in residential location or changes in vehicle characteristics (fuel consumption). Revenue recycling is not considered. Results are presented for combinations of income octiles and residential area.

Fig. 1 shows that the welfare loss increases as a share of disposable income for most of the income range (octile 2-7). The pattern is different for octiles 1 and 8, however. The result for octile 1 should be treated with caution; most incomes in this group are well below the threshold for social welfare in Sweden and therefore cannot really reflect individuals' real access to money. In octile 8, incomes are so high that car use cannot reasonably increase in proportion to income. The regressivity/progressivity of the fuel tax increase is hence different across the income distribution: between octile 2 and 7 it is progressive, but in the low and high tails, it is regressive. The Suits index for the entire income range shows that the fuel tax increase is slightly regressive overall; this is caused by the result for the highest octile. This also hints at why a fuel tax is often slightly regressive in rich countries, but progressive in poor

Figure 1 Welfare loss of the fuel tax increase, relative to income, by type of residential location.

countries: in rich countries, car use in the highest income groups tend to reach a saturation level above which car use only increases slowly when income increases further. This means that a fuel tax' share of income decreases in the highest income segments.

The variation in paid fuel tax across income groups is mostly due to differences in car ownership, and not so much due to differences in car owners' driving distances or vehicles' fuel consumption. This means that if one (for some reason) would consider only car owners, a fuel tax would be strongly regressive (Fig. 1).

Fig. 1 also shows that there are considerable differences between large cities, small cities, and rural areas. A more detailed analysis of shows that residents in satellite cities, which serve as "suburbs" to a region's functional center, pay more in fuel taxes, and that such functional relationships between cities explains more of the variation than just population sizes.

However, these results only present average impact per group, which hides the fact that the variation within each income group is substantial. An income tax will, by definition, affect everyone with the same income in the same way. A car use tax is different: even if it is progressive "on average," there may still be individuals who are hurt disproportionately relative to their income. In fact, a more detailed analysis shows that the share suffering substantial welfare losses relative to their income is much higher in low-income groups than in high-income groups—despite that the average welfare loss relative to income is lower in the lower income groups. This is especially true for low-income groups in rural areas. This may explain the feeling that car use taxes hurt the poor disproportionately: not that they are regressive on average, but that the share who suffer substantial welfare losses relative to their income are higher in lower income groups. That this point seems to be underappreciated is partly a data issue: exploring the variation within groups requires large data sets, and is often impossible without access to registry data, since survey- or modeling-based data sets are usually not sufficiently large.

The argument that members of a group should be affected equally is sometimes called "horizontal equity." How this argument should be applied in the context of car use taxes depends on the purpose of the tax, as argued in the introduction, as this implies how "groups" should be defined. If the purpose is primarily to generate public revenues, it is natural to define "groups" as income segments, and consider distributional effects across and within income groups. If the purpose is to correct the price of car trips, on the other hand, it is natural to define "groups" according to how much people drive, and distributional effects across and within income segments are much less relevant.

Example: Congestion Pricing

Stockholm introduced congestion charges in 2006, first as a trial, and permanently from 2007 (Eliasson, 2008). The charging system consisted of a cordon around the inner city, with charges varying between 2€ in peak hours and 1 € before and after the peaks (nights and weekends are free of charge). The system was slightly revised in 2016, when peak charges were increased and one charging point was added, but the analysis presented here refers to the original system (Fig. 2).

Fig. 3 shows the same as a proportion of monthly income. The data comes from a travel survey (RVU 2015). Income is self-reported total household income before tax, divided by the number of adults in the household. Revenue recycling is not considered. The payment distribution is smoothed through kernel estimation (a generalization of the "moving averages" method).

Average congestion charge payments per person are almost proportional to income, except for the lowest and highest incomes. As before, results for the lowest income groups should be treated with caution, as these incomes are so low that they can hardly reflect available economic resources. In the highest income range, it is as if car use almost reaches a saturation level where it no longer increases with income, and hence payments as a share of income falls somewhat for the highest income range.

Figure 2 Average congestion charges paid per person and day (kernel estimation).

Figure 3 Average congestion charges paid per person and day relative to monthly income (per mille) (kernel estimation).

It is evident from [Fig. 3](#) here that the Stockholm charge is slightly regressive, as charge payments as a share of income falls slowly with income: the overall Suits index is -0.09 . It is also clear from the figures that the slight regressivity is almost entirely due to the results at the extremes of the income range, whereas for most of the income range, charge payments are roughly proportionally to income. Just as for the fuel tax, however, these averages obscure the fact the variation with an income group is substantial.

Analyzing charge payments geographically (not shown here) shows that the congestion charge is more regressive for residents close to the charging zone—especially for residents within the inner city—while it is progressive for residents further away from the zone. This illustrates that the geographical distribution of socioeconomic groups and travel patterns matter, and hence results will differ between cities with different socioeconomic spatial distributions.

A Sample of Empirical Results

The distributional effects of any consumption tax will depend on the local context, and car use taxes are no different. [Table 1](#) shows a sample of empirical studies of distributional effects of fuel taxes, illustrating a representative range of results summarized by Suits indices. In rich countries, fuel taxes tend to be slightly regressive, but the regressivity decreases, if expenditures are used instead of income as a measure of individuals' economic resources. In poor countries, fuel taxes tend to be progressive, and this progressivity also tends to decrease when expenditures are used as a measure of individuals' economic resources. Taking second-order effects of fuel taxes into account affect results mostly to a small extent ([Table 1](#)).

Conclusions

Car use taxes have repeatedly been shown to be very effective policies to reduce emissions and congestion. Few, if any policies can compete in terms of effectiveness, and probably none in terms of economic efficiency.

The distributional consequences of car use taxes will obviously depend on their design and the local context. It is clear, however, that rich groups will pay considerably more per person than poor groups. Considering payments as a share of income, results are more mixed, but broadly speaking, average payments tend to be approximately proportional to income, but slightly regressive in rich countries and slightly progressive in poor countries. The overall regressivity tends to be caused by the outliers: the highest and lowest income groups do not drive quite proportionally to their (registered) income level.

Variation within income groups is often substantial, however. Car use taxes also tend to place a higher burden on residents in rural areas, satellite cities, and urban peripheries, which may counteract societal goals to make such areas more attractive. If the purpose of a car use tax is to generate revenues for public expenditures, variation with income groups, higher burdens in rural areas, and slight regressivity may be viewed as serious problems. After all, it is difficult to defend that poor or rural people should contribute more than proportionally to public expenditures. In this respect, income or general sales taxes can be viewed as more fair, as these by construction take an equal amount from everyone with the same level of income or consumption, respectively.

However, it is much less clear that such distributional effects are relevant if the purpose of a car use tax is to correct the prices of car trips to make them better reflect their full social cost, by for example internalizing the cost of congestion or carbon emissions. Prices of goods and services are usually equal for everyone, for good reasons (most importantly that it leaves it up to individuals themselves to decide how to allocate their resources). Problems with inequitable income and wealth distributions are instead usually (and preferably) handled with general taxes and the social welfare system. Allowing prices of car trips to be lower than their social cost (which they will be in the absence of car use taxes) effectively constitutes subsidies to car drivers from society at large, and these implicit subsidies will overwhelmingly accrue to rich groups. From this perspective, the burden of proof from a distributional point of view lies not on those who want to introduce corrective car use taxes, but on those who defend a situation where car use is effectively subsidized by society. This is of course an even more pressing problem in countries where the price of car fuel is actually subsidized with public money.

Obviously, it can be difficult in practice to figure out whether a particular car use tax should be viewed primarily as a price correction or primarily as a source of public revenue. Nevertheless, the two perspectives are important to keep in mind when drawing conclusions from an analysis.

The Basic Vickrey Bottleneck Model

To introduce the basic Vickrey bottleneck model, consider a hypothetical city with N identical inhabitants who reside in one building and must each commute in their own car to the same workplace along a single road segment, which is prohibited for traffic outside the city. Every where in its stretch, the road is wide enough to serve all the N commuters at a time except at one location, the bottleneck, where at most $\phi < N$ cars can pass at a time. As individuals arrive at the bottleneck continuously in the order in which they depart from home, a queue develops behind the bottleneck from the time when the number of arrivals exceeds bottleneck capacity.

Individuals arrive at work in the order in which they depart from home. The first person to depart from home experiences the shortest travel duration. The travel time for subsequent departures increases as they queue behind the bottleneck. The travel duration in the absence of delay is normalized to zero without loss of generality as it is the same for all individuals. This means that an individual arrives at the bottleneck as soon as he or she departs from home and be at work once he or she exit the bottleneck.

Travel time is undesirable with the cost per unit time spent traveling being $\alpha > 0$. The travel time T associated with departure time d is $T(d) = Q(d)/\phi$, where $Q(d)$ is the number of cars waiting behind the bottleneck (the queue length) at the time of departure from home. That is, the travel time is the ratio of the number of cars queuing behind the bottleneck and the capacity of the bottleneck.

Individuals are assumed to have a preferred arrival time at work, t^* , and that they dislike arriving earlier or later than this time.¹ In addition to the cost of travel time, a commuter incurs $\beta > 0$ per unit time spent at work before t^* and $\gamma > 0$ per unit time after t^* . The extent of earliness and lateness relative to the preferred arrival time are respectively called schedule delay early (SDE) and schedule delay late (SDL). The marginal cost of being late for work is assumed to be higher than the marginal cost of being early, that is $\gamma > \beta$, which is needed for existence of equilibrium.

Individuals choose departure time in order to minimize the generalized cost of the commute trip, which includes the cost of travel time and the cost of schedule delays:

$$\text{cost} = \alpha(a - d) + \beta \max(0, t^* - a) + \gamma \max(0, a - t^*). \quad (1)$$

where a is the arrival time at work and hence $(a - d)$ is travel time, $\max(0, t^* - a)$ is schedule delay early and $\max(0, a - t^*)$ is schedule delay late.

While the ideal departure time from an individual's viewpoint is that which leads to on-time arrival at work without facing a queue, this is however not feasible since other individuals have an incentive to depart slightly earlier in order to avoid delays. Hence, an individual departing at the ideal departure time will spend some time waiting behind a queue and arrive late for work. Let $\hat{d}$ be the departure time that leads to on-time arrival at work. Then, an individual who departs before $\hat{d}$ will be early for work and thus incurs SDE cost. In the same vein, an individual who departs after $\hat{d}$ arrives at work late and will therefore incur SDL cost. Each individual adjusts his or her departure time so long as there is an incentive to do so (Fig. 1).

Equilibrium is obtained when departure time choices are such that no individual can benefit by unilaterally adjusting his or her departure time. Suppose the morning peak period is between times t_0 and t_1 where $t_0 < \hat{d} < t_1$. The equilibrium, which is illustrated in Fig. 1 where the vertical gap between cumulative departures and cumulative arrivals indicates the queue length while the horizontal gap between them shows travel time, has the following properties:

1. The peak period is an interval of time duration which all individuals can pass through the bottleneck, i.e., $t_1 - t_0 = \frac{N}{\phi}$.
2. The first individual to depart from home arrives at work instantly but would be early by $t^* - t_0$.

¹ While the assumption of a homogeneous preferred arrival time was not made in the original Vickrey bottleneck model, the assumption is maintained here for ease of comparison with the literature and to simplify the exposition.

Figure 1 Illustration of the unpriced equilibrium

3. The last individual departing from home will arrive at work instantly but $t_1 - t^*$ time units later than desired.
4. If $\alpha > \beta$, everyone except the first and last individuals to depart from home will face bottleneck congestion.

Equilibrium quantities can be derived from the above conditions noting that, due to homogeneity, trip costs will be the same at all times during the peak period.² Accordingly, the trip cost of the first person to depart from home, hence everyone else by homogeneity, is $\frac{\beta\gamma}{\beta + \gamma} \frac{N}{\phi}$ while the total travel time costs and the total schedule delay costs are each equal to $\frac{\beta\gamma}{2(\beta + \gamma)} \frac{N^2}{\phi}$. It is worth to note the following:

1. While the equality the total travel time costs and the total schedule delay costs is implied only in the simple version of the model, the intuition behind is rather fundamental that travel time represents only part of the total congestion costs.
2. The total travel time costs, total schedule delay costs and hence the aggregate trip cost are each independent of the value of time. The implication of this is that the total schedule delay costs can be determined without knowledge on the value of travel time provided that the start and end times of the peak period are known.

Extensions and Applications

The basic bottleneck model has been applied in various areas and extended in various directions since Vickrey's seminar paper. Below we provide a concise overview of some of these developments. A detailed account of the literature can be found in [de Palma and Fosgerau \(2011\)](#) and [Small \(2015\)](#).

Road Pricing

In the context of the above framework, the social optimum is different from user (or unpriced) equilibrium. The bottleneck model provides an insight into the use of road pricing to manage congestion during the peak period. In the unpriced equilibrium, the waiting time is a pure dead-weight loss, and social optimum can be enforced by introducing a time-varying toll.³ Waiting times under the unpriced equilibrium can be eliminated by implementing the first-best pricing strategy. This involves the imposition of a time-varying toll that is equal to the value of waiting time. Therefore, the generalized costs remain unchanged because the optimal toll exactly replaces waiting time costs, with the collected toll revenue representing a net welfare gain. The starting and ending times of the peak period will remain the same as under the unpriced equilibrium since pricing does not affect the physical capacity of the bottleneck and commuters' work entry time.

While a time-dependent optimal toll is useful for analytical and theoretical configurations, it is difficult to implement in practice as it changes continuously over time. Second-best pricing and coarse toll are often used as an alternative for efficiency and

² We refer interested readers to consult [Arnott et al. \(1990\)](#) for the mathematical derivation of equilibrium quantities.

³ The bottleneck model has been used to analyse strategies for reducing traffic congestion that resulting in welfare loss under user equilibrium without government intervention. Some of these strategies include the introduction of tolls and parking prices at workplace.

practicality. In particular, second-best pricing has many variants that differ in terms of sources and constraints. It has less welfare gains than first-best pricing but provide implications for the attainment of multiple policy objectives relating to congestion management, cost-benefit analysis and market shares.

Valuation of Travel Time Variability and Travel Information

In the bottleneck model, equilibrium is obtained assuming that drivers have complete information about traffic situations. However, this is not often the case as travel times tend to be unpredictable from a commuter's point of view. When travel times are unpredictable, the arrival time of a particular trip cannot be known with certainty ahead of the trip. A behavioral response to account for the random variation in travel times includes leaving a safety margin at the beginning of the trip. In so doing, travelers trade the inconvenience of departing earlier and potentially being at work earlier than desired for a higher probability of arriving on-time. The higher the degree of randomness in travel times, the earlier the commuter needs to depart in order to maintain the same probability of arriving on-time.

The customary scheduling model for the valuation of travel time variability (Small, 1982) applies the same $\alpha - \beta - \gamma$ formulation of travel time and scheduling costs as that in the bottleneck model in order to analyze scheduling choices and ultimately derive a measure of the cost of travel time variability. An empirical estimate of the resulting measure of the cost of travel time variability has been used in traffic demand modeling and as input in economic appraisal of transport infrastructure and policy.

Heterogeneity in Values of Time and Preferred Arrival Time

Empirical evidence shows significant heterogeneity in trip-timing preferences across individuals. Indeed, the value of time and preferred arrival time could vary with flexibility of working hours, trip purposes, and similar other socio-economic factors. For commuting trips, empirical studies indicate that the differences in preferred arrival times come from the heterogeneity in work hours, trip-timing of daily activities, sleeping time preferences and so on. The seminal paper by Vickrey (1969) and early derivations of the bottleneck model capture the heterogeneity in preferred arrival times. For instance, Vickrey (1969) assumed a uniform distribution of preferred arrival times. Subsequent research has further generalized this for continuous and discrete nonidentical scheduling preferences. The discussion in the previous studies indicate that a certain fraction of travelers will only travel early or late for work based on the distribution of preferred arrival time and the fixed capacity.

In addition to the aforementioned factors, differences in the values of travel time and schedule delays are also attributable to heterogeneity in work hour flexibility. Elaborations on the heterogeneous values of time in the literature imply that the equilibrium arrival pattern will be sorted accordingly to their ratios $\frac{\beta}{\alpha}$ and $\frac{\gamma}{\alpha}$. For instance, suppose commuters have different unit cost of travel time but the same unit costs of schedule delay early and schedule delay late. In equilibrium, commuters arrive in different time intervals such that the group with higher unit cost of travel time (lower ratio) is traveling toward the end of the peak period.

User heterogeneity steps forward to more realistic generalizations of the bottleneck model and is important for determining and evaluating the welfare effects of toll strategies and capacity expansion. It also helps in understanding the choices of routes in a network where individual routes are characterized in terms of free flow travel time, tolls, congestion costs, and similar other features.

Networks

In fairly crowded areas, travelers might observe two or more bottlenecks in a network. In the case of configurations of upstream and downstream bottlenecks in series, travelers' departure times are socially non-optimal thus aggregate trip costs can be reduced by limiting the upstream effective capacity. This reveals the Braess paradox, in which expanding capacity to existing links in the network can result in increased aggregate travel costs. Previous studies also evaluated the use of entry-ramp metering in order to restrict the upstream flow and can thus improve efficiency. Previous research also considered parallel bottlenecks which can be different routes or different lanes of a single route. The parallel bottleneck models construct the opportunity to explore partially tolled express lanes.

The literature also analyzed a more general network with demand assignment and congestion costs among various origins and destinations. In one of the studies in this literature, the marginal values of travel time and schedule delay costs, i.e., α , β and γ are defined in relation to trip destinations and both travelers' route and departure time choices are determined. In this setting, system optimum can be achieved with time-dependent tolls by a space-time expanded network. This approach of dealing with queuing networks could provide many practical insights on traffic congestion over both space and time.

Other Application Areas

Agglomeration: In the basic bottleneck model, scheduling preferences are assumed to be exogenous and the value of time spent at the origin is assumed to be fixed irrespective of the time of the day. It is not clear how scheduling preferences arise and that the value of time spent at home may depend on when it is spent. Fosgerau and Small (2017) extend the basic bottleneck model and showed how scheduling preferences can arise as a result of agglomeration benefits at work and non-work activities performed at either ends of the trip.

METROPOLIS Model: A number of studies aim at establishing and developing simulation models to analyze a real city, such as the METROPOLIS. The METROPOLIS provides a dynamic environment to capture departure time and route choice behavior in a

large-scale network. Individuals are assumed to minimize their generalized travel cost function that depends on schedule delay costs, queuing costs and travel time cost. Route and departure time choices are thus endogenously derived at equilibrium. The system is capable of integrating additive elasticity, heterogeneity and variability in terms of capacity or demand as illustrated in the aforementioned sections, which provide tractable simulations on large-scale and real cases. The METROPOLIS system is established for both within-day and day-to-day dynamics of real network. It can provide a fully dynamic tool to evaluate strategies and pricing schemes for multiple policy objectives relating to demand management, such as smoothing out peak hour demand, increasing commuters' satisfaction and inferring commuters' travel patterns.

Parking: Parking is a growing topic due to the increasing urban population and traffic congestion. The basic bottleneck model has been augmented to analyze the choice of parking spots that differ from one another based on their location and the fee involved. In unpriced equilibrium, the first commuter passing through the bottleneck choose the closest parking spot to destination which is inefficient. In contrast, a location-dependent parking fee schedule can induce commuters to park in order of decreasing distance from destination, thereby reducing schedule delay costs. A variety of researchers also analyzed the parking setup with bottleneck model from different perspectives such as cruising, search, spot reservation and so on. The bottleneck model provides a straightforward foundation to analytically discuss and quantify the impacts of parking on urban mobility and congestion.

Land use: Land use incorporating bottleneck model is often formalized with suburb and downtown areas where travelers commute between the two areas. The situation describes commuting congestion considering the travel distance from residential locations to the bottleneck. At the equilibrium with homogeneity, commuters are sorted depending on their travel distance such that those who live closest to the bottleneck arrive to the destination first. The optimal coarse tolling benefits commuters who lives beyond a critical distance and induce a loss for nearby commuters. While with heterogeneity of values of time, commuters also sort temporally according to the ratio of unit cost of schedule delay early and late (i.e., $\frac{t}{\tau}$). Those with lower ratio value tend to arrive closer to their preferred arrival time to avoid queuing time rather than a schedule delay. Some researchers argue that when considering heterogeneous commuters, the socially optimal tolling expands the suburb populations and rent which hurts low-income communities residing in the suburb.

Autonomous vehicles: With the development of new technology and systems, the bottleneck model has new forms of settings and insights related to queuing formulation, value of time, system capacity and so on. For instance, carpooling and autonomous vehicles change user travel patterns and behaviors, resulting in different dynamic travel delay and congestion from the basic model. Recent research have used the bottleneck model for these purposes. Recently, [van den Berg and Verhoef \(2016\)](#) augmented the bottleneck model to explore the effect of autonomous vehicles on capacity, values of time and heterogeneity.

Conclusion

The bottleneck model is a fundamental tool for analyzing the phenomenon of traffic congestion and predicting the effect of transport-related policies on social welfare and traffic congestion. The model has attracted extensive attention in the last 50 years to become a standard tool for understanding traffic congestion and evaluating the effect of policies affecting it. The basic Vickrey bottleneck model has been extended in various directions and applied in numerous areas. The model continues to provide theoretical insights in economics and empirical applications. While issues discussed in the previous section can be explored in other frameworks, the bottleneck model has proven to have analytical properties to provide a formative and in-depth point of reference for researchers and practitioners in transportation analysis and modeling.

Introduction

The bottleneck model is a powerful tool for analyzing traffic congestion. In the chapter on the bottleneck model, it became evident that queueing in front of a bottleneck can be avoided with optimal pricing. Commuters change their departure times and, instead of wasting time stuck in a traffic jam, they pay a user charge. There is no waiting time wasted and all commuters are better off than before.

In reality, commuters differ from each other (are heterogeneous) and thus new aspects come into play. Heterogeneity means that users prefer different arrival times, have different incomes, and have different trip purposes. For this reason, several important parameters of the bottleneck model, like the desired arrival time, waiting, and schedule delay costs, are no longer equal for all commuters, but depend on individual characteristics and on trip purpose.

In this chapter, we will briefly explain dynamic congestion pricing and discuss the sources of heterogeneity among road users. If users with different characteristics and preferences are faced with congestion charges, some groups of road users are affected more than others. Understanding and mitigating these effects on different user groups is of considerable importance to increasing the political acceptability of congestion charges.

Dynamic Congestion Pricing

The first approach to analyzing the effects of traffic congestion was from [Arthur Pigou](#), who used the example of congested roads to explain external effects. Drivers assume that the travel conditions are independent of their own behavior and consequently, they only consider their average costs and not those they impose on other drivers. The no-toll equilibrium is at the intersection of the demand and the average cost functions. However, because there are also external costs, such as my decision to drive on the road increasing traffic and also slowing down other drivers, the no-toll equilibrium does not lead to the social optimum. Imposing an optimal user price p , which equals the marginal external costs in the optimum, reduces the demand to the socially optimal quantity. A graphic illustration can be found in [Santos and Verhoef \(2011\)](#). Ultimately, this charge increases the trip costs so that those drivers with the lowest willingness to pay will no longer travel and trips with a low priority will no longer be made. This Pigouvian charge efficiently reduces the traffic volume to the optimal quantity. As a result, however, before the reallocation of charges, all drivers are worse off than before, as the drivers who are priced off the road, as well as those who still use the road and pay the charge, lose utility from congestion pricing.

The Pigouvian congestion charge is based on a static model, which delivers valuable insights, but fails to depict traffic demand that varies over the course of the day. In order to capture this dynamic feature of traffic conditions, [Vickrey \(1969\)](#) introduced the so-called bottleneck model, and [Arnott et al. \(1990\)](#) developed an equilibrium model to investigate various toll regimes. This model is described in detail in the chapter on the bottleneck model. We will therefore only review those aspects of the model that are relevant to understanding the impact of user heterogeneity.

The model is based on a fixed number of homogenous commuters who drive to work during the morning rush hour. All commuters have to pass through a bottleneck with a fixed capacity s and want to start work at the time t^* ([Arnott et al., 1990](#)). Trip costs consist of α , β , and γ and, if introduced, a toll. While the parameter α displays the waiting costs, the parameters β and γ are the

schedule delay costs. β is the shadow value for being early and γ is the shadow value for being late (Arnott et al., 1993). Schedule delay costs mean that due to congestion, people do not drive at their preferred times and thus have to change their daily routines, such as getting up earlier in the morning to avoid congestion. Except for the first and the last commuters, who only incur schedule delay costs, all other commuters are faced with both schedule delay and waiting costs. At equilibrium, the trip costs for all drivers must be equal, because otherwise, individuals could change their departure time to reduce their costs.

The time-varying toll is proportional to the waiting costs and increases until t^* and decreases afterward. The optimal toll changes the departure times in such a way that there will be no queue in front of the bottleneck and consequently no waiting time. The toll transforms waiting costs into government revenues, which can be used to make a lump sum redistribution to commuters, to improve public transport, or to increase road capacity. Without any productive use of the revenues, the toll would be economically neutral. If money is invested, at least to some degree, in useful projects, everyone could be better off.

A quite new type of congestion models are the so-called bathtub models developed by Arnott (2013). Bathtub models consider the downtown urban center in an aggregated fashion. This seems to be a realistic view of urban congestion, because in heavily congested urban centers, it becomes difficult to identify single bottlenecks in the rush hour, as the whole city appears to be jammed. Both the bottleneck and the bathtub models are thus capable of handling hypercongestion. Moreover, bathtub models combine the fundamental relationship between speed, flow, and density from transportation science with important features of dynamic economic models, for example, bottleneck model.¹ This means, for instance, that total trip costs consist of travel time costs and schedule delay costs, as in the bottleneck model. In contrast to the latter, where the discharge rate of the bottleneck is not affected by the length of the queue in front of the bottleneck, in the bathtub model, however, the discharge rate of the congested downtown urban center is reduced if traffic density exceeds a critical level. This is in line with the fundamental relationship.

As in the bottleneck model, in the bathtub model, the optimal time-varying congestion charge should ease congestion. In the bottleneck model, the commuters' departure times are changed in such a way that the queue in front of the bottleneck is eliminated. In the bathtub model, the time-varying toll should keep traffic density below a critical value to avoid hypercongestion. This is especially important, as the (out)flow rate should be kept high to maintain an efficient road network performance.

The efficiency gain of tolling depends on the extent of congestion in the urban center. When congestion is low, the efficiency gain may be lower than the revenues; when congestion is strong, the efficiency gain may be substantially higher than the revenues (Arnott, 2013). If the latter is the case, congestion tolling may be beneficial even, if toll revenues are invested entirely in pointless projects. This insight for heavily congested downtown urban centers might increase the political acceptance of congestion tolling. Accordingly, this latter point also reveals an important difference to the bottleneck model, where the efficiency gain from tolling exactly equals the toll revenues.

Economic models in general, when dealing with a topic that has not been analyzed before, usually start off with a series of assumptions that make the models tractable. Models for congestion pricing initially depart from inelastic deterministic demand, no outside option like public transport, deterministic capacity, as well as homogeneous users (Arnott, 1990). While the bottleneck model has been used for decades as a tool for analyzing bottleneck congestion, it has already been extended in several respects, and various assumptions have been relaxed. Bottlenecks have, for instance, been analyzed with elastic demand (Arnott et al., 1993; Yang and Huang, 1997), stochastic capacity (Xiao et al., 2015), as well as heterogeneous commuters (Arnott et al., 1994; Takayama and Kuwahara, 2017). In the bathtub model, most of the extensions are still open for future research (Arnott, 2013; Fosgerau, 2015). Later on, we will illustrate the effects of heterogeneous users in the bottleneck model with a numerical example.

In the next section, we take a close look at the characteristics and preferences that make users differ from each other. We furthermore demonstrate how this heterogeneity is dealt with in economic models.

User Heterogeneity

Determinants of Trip Costs

In this section, we take a close look at user heterogeneity. Drivers may be shift workers, employees in IT start-ups, parents picking up their child from a table tennis lesson, or taxi drivers. We can see from these examples that there are various reasons to make car trips during the rush hour. All these users have different preferences, and thus different values of travel time and different costs of schedule delay. It is, for example, not unlikely that if we asked the drivers of 300 cars passing a highway traffic detector for their willingness-to-pay for the trip, we would observe 300 different travel time values. Although there are some important factors that impact on the value of time, it remains difficult to isolate all origins of heterogeneity (Brownstone and Small, 2005).

The value of time depends on the opportunity costs of time and the direct utility of travel time. When stuck in a traffic jam (waiting costs) or starting a trip to work earlier or later to avoid the traffic jam (schedule delay costs), you could have been doing something else during this time. If there had been no congestion, you could have been at work 1 h earlier, and the opportunity costs are your hourly wage. Alternatively, it would have been possible to start the trip to work 1 h later and use the time to sleep longer in the morning. The value of this 1 h more sleep in the morning, although this is your free time, can be substantial, as well. Consequently, it depends on the value that people assign to what else they could have been doing during that time. Although values of time are very individual, there are some factors that at least on average influence time values systematically. These are, for example, income and trip purpose (Santos and Verhoef, 2011).

¹ For more information on the fundamental relationship, refer to the Chapter "Speed-Flow-Density and Dynamics of Congestion".

User heterogeneity leads not only to different values of travel time but also to different preferences regarding the arrival time t^* . There are people working in hospitals who begin their early shift at 6.00 a.m. in the morning, and there are those working in a shop in the downtown urban center that opens at 10.00 a.m. in the morning. As we can easily see, different preferred arrival times can at least to some extent smooth the demand for road capacity and can thus also moderate traffic congestion.

Real-Life Heterogeneity and Its Effects on the α , β , and γ Parameters

Income

The value that people assign to their time turned out to depend heavily on income. That is, people with higher income usually have higher values of time (Börjesson et al., 2012; O'Flaherty, 2005). This is readily understandable when we consider that one additional hour available could have been spent at work. In the short run, however, most employees have fixed working hours and they cannot decide freely how many hours they work each day. In contrast, at least in the medium- and long-run, hours spent at work and hours of free-time are substitutes. A person who presently has long working days can change his/her job and start a new one where he/she can work 1 h less per day than before. The payment forgone due to this hour more of free-time per day is the opportunity cost. Consequently, the value of your free-time is also closely tied to your income. The higher the income, the higher the value assigned to time in general.

A thought experiment can illustrate this: If we consider two people, the first person with an annual income of 30,000€ per year and the second with an annual income of 200,000€ per year. Person 1 is paid 16€/h and person 2 receives 109€/h. If both could buy 1 h more free-time per day for 15€, person 1 will probably not accept this offer as he/she loses about the amount he/she earns in 1 h, while person 2 only has to pay about one-eighth of his/her hourly wage. When the optimal toll in the bottleneck model that avoids queuing is 15€/h, and the time lost due to congestion per day is 1 h, we can immediately see the effects of congestion pricing. Person 1 would probably prefer to pay with waiting time instead of 15€, while person 2 would probably prefer to pay 15€ to cut his/her commuting time and gain one more hour of free-time. As congestion charges are usually not tied to income, we can see that people with different incomes are affected very differently by congestion charges.

The preferences α (waiting time costs), β (time costs of being early), and γ (time costs of being late) in economic congestion models depend on the value people assign to time. As illustrated above, the value people assign to time depends on income. For this reason, we can conclude that all time cost parameters (α , β , γ) depend positively on income. If we assume that all other factors (trip purpose, sex, age, . . .) are equal, high-income individuals will have a higher value of time, compared to those with low income.

Trip Purpose

Trip purposes can be split into private and business. Private trips may entail commuting to the workplace or school, or driving to the supermarket, the zoo, or to the guitar lesson. As we can see from these examples, especially the values for schedule delay costs of being late γ differ considerably between the different trips.

The highest schedule delay costs might be those for work trips with a fixed start time followed by the guitar lesson. When you are 30 min late to a 45-min guitar lesson, the whole trip might become pointless. Workers with flex-time might be more relaxed, provided the delay is not too long. For free-time activities without a predetermined starting time t^* , in this case driving to the supermarket or to the zoo, we probably have low schedule delay costs of being late.

Being early imposes lower costs on average. The order regarding the costs of the examples for trips mentioned above probably remains the same.

Another type of trips are those during working time. Business trips are related to the job and can, for example, mean driving to the customer or to the airport to catch a plane to fly to a transport economics conference. Being late at a customer is on average bad, but being late at the airport and running the risk of missing the plane, is surely worse. The costs of being early might be the reverse. If you are a frequent flyer and can spend time being early in the airport lounge, this might not be so bad, while waiting in the car in front of the customers company might be rather unproductive time. Yet, these costs might also be perceived differently by different individuals.

Taxes and social insurance contributions split up the gross wages paid by an employer and net wages received by an employee. Waiting costs for trips with a business purpose usually comprise gross wages and are therefore much larger than waiting costs for private trips (e.g., commuting to the workplace), even if the affected person in the car is the same. People using private cars have to pay tolls from their net wages. Company car drivers usually do not pay tolls themselves, but obtain a refund from the company. As long as the company only partially refunds tolls, drivers of company cars will probably not consider changing their behavior to avoid tolls.

In contrast to the situations described above, driving may also be the purpose itself. Some people simply like cruising around or making a round trip on their motorbike. As there is then no destination to reach at a specific time t^* , there are no schedule delay costs. Regarding the waiting costs α , there are reasons for their being both low or high. One can, on the one hand, argue that such persons usually enjoy their time inside the car or on a motorbike so that waiting costs might be relatively low. On the other hand, being stuck in a traffic jam might also be annoying because driving is a lot less fun in such a situation.

As we can see from the above examples, trip purposes mainly differ from each other regarding their costs of schedule delay, β and γ . Waiting costs α do not depend so much on the trip itself, but rather on personal characteristics. This is basically the income, but can

Table 1 Summary of effects

Parameter	Trip purpose	Waiting/SDCs	Impact
High income	All	α	High
	All	β and γ	High
Trip purpose	Trip to airport to catch plane	β	Medium
		γ	Extremely high
	Visit the zoo	β	Low
		γ	Low
	Driving itself	β	None
		γ	None

also, for example, be the person's general patience or impatience. Possible influences on the α , β , and γ parameters are summarized in **Table 1**.

Further Influences on the Value of Time

Further systematic influences might also be age and sex. However, when going into detail, it becomes obvious that much of the influence can again be attributed to income and trip purpose. While younger people might have more obligations, like going to school or to work, people who are retired, do not have generally such a packed daily schedule and might thus have on average lower schedule delay costs. But elderly people can also have trip purposes with high schedule delay costs. The on average lower income compared to employed people might also influence waiting costs negatively.

A user of an autonomous car has reduced travel time and waiting costs (α), as the time inside the car is not used for driving the car and can be used productively or for entertainment. This can worsen congestion in the rush hour, as waiting is not perceived so negatively by commuters. Now, we can see that the various aspects discussed above can be combined in every conceivable way. People considered in this section could use carpooling and therefore, their waiting and schedule delay costs might be about twice as high as for single drivers. Or a 35-year-old woman with a high income, living in a suburb, may be driving to the zoo with her child. In this example, we observe a person who generally has a high value of time, but in this case, a trip purpose with low schedule delay costs. For this reason, [Van den Berg and Verhoef \(2011\)](#) argue that gains and losses from tolling are not monotonic in the value of time because there are also very different values of schedule delay costs.

User Heterogeneity in the Bottleneck Model

In this section, we take a close look at heterogeneous users in the bottleneck model, based on the paper from [Arnott et al. \(1994\)](#). We describe the effects of dynamic congestion pricing on heterogeneous users by means of a numerical example.

When we introduce heterogeneous users in congestion models, we have to consider several α , β , γ parameters. The preferred arrival time t^* is equal for all commuters at this point ([Arnott et al., 1994](#)). For illustration purposes, we distinguish between three groups of users: Group L with a low income, group M with a medium income, and group H with a high income. For our numerical example, we assume that $N = 6000$ commuters want to drive through a bottleneck with a capacity of $s = 2000$ cars/h. To pass through the bottleneck, the commuters thus need 3 h. Each group (L, M, H) consists of 2000 commuters, which means that each group requires 1 h to pass through the bottleneck. The preferred arrival time is $t^* = 8:00$ a.m. Furthermore, all model assumptions made by [Arnott et al. \(1994\)](#) are valid for this example. The parameters we assume for our numerical example are summarized in **Table 2**.

To determine when each group prefers to travel, we need to know the relative disutility of schedule delay relative to travel time (β/α) for each group. The group which does not mind waiting in the traffic jam at the center of the peak period, but seriously dislikes schedule delay will travel in the middle of the peak period. The group in our example that dislikes schedule delay most, relative to waiting, is group L ($\beta/\alpha = 0.80$). A common example is the assembly line worker, who starts his/her shift at a certain fixed time

Table 2 Parameters for three groups of commuters

Parameter	Group L	Group M	Group H
α	0.10	0.30	0.70
β	0.08	0.20	0.40
γ	0.16	0.40	0.80
β/α	0.80	0.67	0.57

Cost parameters are defined in €/min.

Figure 1 Departure times in the no-toll equilibrium.

(Arnott et al., 1994). If he/she is at work early, there is nothing to do until the shift starts and schedule delay costs are high, and if he/she is at work late, schedule delay costs are very high indeed, because production might come to a standstill. Of course, there are also employees with fixed working times and a high income, like doctors working in hospitals. However, it seems that there are more people with a high income who have flexible working times compared to people with a low income and flexible working times (Lott, 2016, p. 9). Therefore, it can also be assumed that on average the relative costs of schedule delay to waiting costs decrease with income ($0.80 \geq 0.67 \geq 0.57$) as displayed in the example in Table 2. As shown in Fig. 1, drivers of group L will drive in the middle of the rush hour and those of group M at adjacent times, and drivers of group H, with the lowest relative costs of schedule delay, will travel at the fringes.

We can also calculate the costs for each group in the no-toll equilibrium. The first driver arriving at the bottleneck at 6:00 a.m. incurs only schedule delay costs and no waiting costs. Schedule delay costs of group H are $\beta_H = 0.40\text{€/min}$. Because they arrive 120 min (8:00–6:00) too early, total costs are 48€. Since, in equilibrium, each point in time for the homogeneous group H must be equally attractive—otherwise people could still change their departure time to reduce their costs—the costs of all drivers of this group must be equal. The last driver of group H who is early at 6:40 a.m. also has 48€ of total cost of which 32€ are schedule delay costs and 16€ are waiting costs.² The same applies to drivers of group H who are late. The last driver is 60 min late and has schedule delay costs of 0.80€/min ($60 \text{ min } 0.80\text{€/min} = 48\text{€}$).

The first driver of group M arrives at the bottleneck at 6:40 a.m. He/she is 80 min early and has schedule delay costs of being early of 0.20€/min , which leads to schedule delay costs of 16€. As calculated in Footnote 2, waiting time in the queue at that time is approximately 23 min. 23 min multiplied by the waiting costs of drivers of group M (0.30€/min) causes waiting costs of $\approx 7\text{€}$. Thus, total costs of group M are 23€.³

As the drivers in group L have the highest relative cost of schedule delay, they thus arrive at the center of the rush hour. The first person to arrive at the bottleneck is 40 min early and has schedule delay costs of 8 cents/min and thus total costs of schedule delay of 3.20€. The waiting time at that arrival time is with 50 min⁴ relatively high and the waiting costs are: $50 \text{ min } 0.10\text{€/min} \approx 5\text{€}$. Finally, total costs of group L are 8.20€. Fig. 2 summarizes the commuting costs of the no-toll equilibrium.⁵

We can see in the no-toll equilibrium that schedule delay costs for group H are relatively high because they have the highest costs of schedule delay per minute and travel at the least attractive times.

We now assume that a toll is introduced to avoid waiting times in front of the bottleneck. In contrast to the no-toll equilibrium, the absolute schedule delay costs now matter. This is because people pay for using the road at a specific point in time, and will only travel at that time, when their schedule delay costs of traveling at another time are higher. In other words, drivers have to pay money to reduce schedule delay. As the toll is equal for all drivers, but schedule delay costs depend on income, high-income drivers will be more willing to pay the toll to avoid/reduce schedule delay.

When we now order our three groups of drivers in terms of their absolute schedule delay costs, they will change their positions (Fig. 3). Group H has the highest absolute schedule delay costs ($\beta = 0.40\text{€/min}$) and will travel in the middle of the rush hour. The adjacent times will be used by group M ($\beta = 0.20\text{€/min}$) and group L will travel at the fringes ($\beta = 0.08\text{€/min}$). In this social optimum, total schedule delay costs are minimized because the drivers with the lowest schedule delay costs per minute have the longest schedule delay and vice versa.

The example shows the main features of income heterogeneity in the bottleneck model. Whereas in the no-toll equilibrium the most attractive arrival times are used by low-income people paying with their waiting time, the toll shifts the low-income people to the fringes of the rush hour and high-income people travel at the most attractive times.

In the social optimum, group L travels at the fringes, and the total costs incurred by group L can again be calculated with the first and the last drivers. While the first driver is 120 min early and has schedule delay costs of $\beta = 0.08\text{€/min}$ he/she has costs of 9.60€ (last driver: $60 \text{ min} \cdot 0.16\text{€/min} = 9.60\text{€}$). Since the total cost incurred by group L is 9.60€, the last driver of this group being early at 6:40 a.m. has schedule delay costs of $80 \text{ min} \cdot 0.08\text{€/min} = 6.40\text{€}$. The congestion charge he/she pays is: $9.60\text{€} - 6.40\text{€} = 3.20\text{€}$. The same applies to the first driver of group L who arrives late at 8:40 a.m.

The congestion charge at 6:40 a.m. is 3.20€. The first driver of group M to arrive at 6:40 a.m. thus pays this charge as well and has schedule delay costs of $80 \text{ min} \cdot 0.20\text{€/min} = 16\text{€}$. As all drivers in this group are equal, they all incur total costs of $3.20\text{€} + 16\text{€} = 19.20\text{€}$, although the composition of costs may differ. The closer drivers of group M arrive to t^* , the lower the schedule delay costs become

² The 16€ waiting costs can be derived the following way. The last driver of group H before 8:00 a.m. is 80 min early (8:00–6:40). This amounts to schedule delay costs of $80 \text{ min} \cdot 0.4\text{€/min} = 32\text{€}$. The difference is $48\text{€} - 32\text{€} = 16\text{€}$ waiting costs. Consequently, the waiting time at 6:40 a.m. is $16\text{€}/0.7\text{€/min} \approx 23 \text{ min}$.

³ The same applies to all the members of group M who are late and where the last driver arrives at 8:40 a.m. Calculation: $40 \text{ min} \cdot 0.40\text{€/min} + 23 \text{ min} \cdot 0.30\text{€/min} = 23\text{€}$.

⁴ The waiting time can again be calculated analogous to Footnote 2 with the costs of the last early driver (or first of the group of late drivers) of group M.

⁵ In Figs. 2 and 4, schedule delay costs are labeled SDC and waiting/travel time costs are labeled WC.

Figure 2 Departure times and costs in the no-toll equilibrium.

Figure 3 Departure times in the social optimum.

and the higher the toll becomes. The last driver of group M, being early at 7:20 a.m., has schedule delay costs of 8€ (40 min 0.20€/min) and pays a toll of 11.20€ (19.20€–8€). Again, the first driver of group M, being late, incurs the same composition of costs.

As the first driver of Group H who arrives at the bottleneck at 7:20 a.m. pays a toll of 11.20€, and has schedule delay costs of 40 min 0.40€/min = 16€, all drivers of group H have total costs of 27.20€. The driver of group H who arrives at 8:00 a.m. only pays the toll and has no schedule delay costs, as he/she arrives at his/her preferred time. Fig. 4 summarizes the effects.

The high-income group travels at the most attractive times and pays the highest congestion charges. Compared to Fig. 2, the areas of schedule delay costs are smaller now because the high-income group with high schedule delay costs per minute now travels close to 8:00 a.m.

Before redistribution of the toll revenues, commuting costs change as displayed in Fig. 5: Whereas the high-income group gains 48€ – 27.20€ = 20.80€ per commute, the low-income group loses 9.60€ – 8.20€ = 1.40€. A congestion charge that is personalized and, for example, tied to income could remedy this problem, but connecting travel data with income data of course raises new problems regarding data protection and privacy.

In our numerical example, total user costs would shrink from $2000 \cdot 8.20€ + 2000 \cdot 23€ + 2000 \cdot 48€ = 158,400€$ in the no-toll equilibrium to 112,000€ ($2000 \cdot 9.60 + 2000 \cdot 19.20 + 2000 \cdot 27.20$) in the optimal toll equilibrium. However, the whole picture of welfare effects is incomplete without knowing how the toll revenues are spent and including the costs for collecting the toll. The following utilizations are usually addressed: lump sum redistribution, tax cuts, improve or increase subsidies for public transport. A lump sum redistribution of the toll revenues of 56,000€ reduces user costs to 56,000€ (because the toll revenues are half of total costs), about a third of the no-toll equilibrium.

Low-income groups, fearing that redistribution will not compensate for losses, will oppose the proposed toll regime. A popular political remedy is using the toll revenues to subsidize public transport. Former car drivers shifting to public transport reduce the length of the rush hour and therefore waiting as well as schedule delay costs. We can now consider a low-income person with

Figure 4 Departure times and costs in the optimal toll equilibrium.

Figure 5 Commuting costs.

commuting costs of 8.20€ at the status quo no-toll equilibrium and with no opportunity to shift to public transport. In order to have no more costs than 8.20€ in the toll equilibrium, the toll must not start before 6:17:30 a.m., because at this time, schedule delay costs are $102.5 \text{ min} \times 0.08\text{€} = 8.20\text{€}$. All car drivers passing the bottleneck before 6:17:30 a.m. have to use public transport to secure nonrising commuting costs for low-income people. Comparing 17.5 new low-income minutes with 40 min shows that $17.5/40 = 43.75\%$ of the low-income group has to shift their transport mode, if public transport subsidies lead only low-income people to use public transport. Low-income group members who fear that the subsidies are not large enough to induce such a modal shift, or assume that public transport capacities are too low for the new travelers, will oppose a toll, even if the proposal earmarks the toll revenues for public transport.

For a more detailed perspective on the distributional effects of congestion charges, also see chapter “Distribution effects of congestion charges and fuel taxes.”

Further Aspects

As already pointed out in the discussion on heterogeneity, users of autonomous cars have reduced travel time values, as the time in the car can be used productively or for entertainment. [Van den Berg and Verhoef \(2016\)](#) have extended the bottleneck model for

autonomous cars and find two opposing effects. On the one hand, due to reduced travel time/waiting costs, users tend to drive closer to t^* and thereby worsen congestion (heterogeneity effect).⁶ On the other hand, autonomous cars require smaller headways and thus road capacity increases (capacity effect). This second effect eases congestion. As long as the market penetration of autonomous cars is low, the heterogeneity effect is likely to dominate and congestion in the rush hour will increase.

The bottleneck model has been extended by Yu et al. (2019) to another aspect of heterogeneity, namely carpooling. Commuters of the groups considered above with a similar origin and destination could share one car (within their group). This results, for example, in two people traveling in one car. The impact on the departure times in the bottleneck model is straightforward. It leads to carpool cars with twice the schedule delay costs, compared to a single driver of the same group. Analogously to our example, in the social optimum, commuters with the highest values of schedule delay costs will drive closest to the preferred arrival time. If income differences are large ($\beta_H > 2\beta_L$), the early arrival order will be: group L solo drivers, group L carpoolers, group H solo drivers, and group H carpoolers. If income differentials are small, ($\beta_H < 2\beta_L$), the arrival order before t^* will be: group L solo, group H solo, carpoolers of group L, carpoolers of group H. Because carpooling generally eases congestion, but a large share of benefits also accrues to solo drivers, Yu et al. (2019) propose a subsidy for carpooling.

In the long-run, preferences for living style (rural or urban) have an effect on the decision as to where to locate. The location matters when introducing congestion pricing, as people living in the central business district, in the midtown, or in the suburbs are affected differently by the toll (de Borger and Russo, 2018). Congestion pricing also affects landowners and renters differently (de Borger and Russo, 2018). How these groups are affected by congestion pricing also depends on the system introduced (e.g. cordon toll, area toll). Moreover, the distance from home to the next bus stop or railway station and the public transport's level of service is a further source of heterogeneity, which is reflected in rents or land prices, and may lead to self-selection.

Conclusion

Drivers on a congested road differ in many respects, for example trip purpose and income. Besides personal characteristics, people also differ regarding their preferences for solo-driving, carpooling, or using autonomous cars. All these aspects impact on people's schedule delay and waiting costs. Whereas for a no-toll road, the relative values of schedule delay costs and waiting costs determine at which time a driver arrives, in the optimal toll equilibrium, absolute values of schedule delay determine the arrival times. If income is the only source of heterogeneity, the low-income people use the most attractive arrival times if there are no tolls. The optimal toll shifts the low-income people to the fringes of the rush hour, and the high-income people drive at the most attractive times. Furthermore, people with a trip purpose with high schedule delay costs will also use the most attractive times. Before redistribution of the toll revenues, low-income drivers may prefer a no-toll equilibrium, because they value the gains of no more waiting time less than the disadvantage of unsuitable arrival times and toll payments. However, the toll is a potential Pareto improvement, meaning that if toll revenues are spent wisely, all commuters gain from the optimal toll regime.

Introduction

The Economics of Parking is the branch of transport economics that deals with parking, that is, the bringing to a halt of a vehicle—generally a motor vehicle—and leaving it temporarily unoccupied in a dedicated space of the urban area, which might be either at the curbside or in a facility/building off the street (either public or private garages). Unlike most transportation research and policy analyses that concern themselves with situations in which vehicles are in motion, the Economics of Parking considers the most usual state of cars, given that they are parked for about 95% of the time. As such, the issues typically addressed in the Economics of Parking are the efficient allocation of urban space to parking; parking regulation, planning, and pricing; the indirect distortions that parking produces in the functioning of other markets; and the derived externalities that may affect social welfare. Recent social and academic interest in smart and sustainable mobility in cities has boosted economic research in parking in a variety of areas.

Free or low-cost parking fuels excessive demand and creates negative externalities, and supply-oriented policies result in the massive consumption of urban space dedicated to parking, reducing parking costs and promoting the use of private vehicles by favoring their relative attractiveness. If parking is underpriced, then its costs will inevitably be hidden in the price of everything else in the city (Shoup, 2005). The social costs of underpriced parking include greater congestion and pollution, a higher number of accidents, and a greater amount of time wasted, primarily as a result of inefficient parking policies and regulations. Current concerns about sustainable mobility mean that parking is increasingly being understood as a tool for mobility while stressing the importance of accounting and addressing its market distortions. This understanding has fuelled initiatives to reorient planning toward a parking demand management approach, where parking is planned in order to serve wider urban and transport policy goals. One such goal is typically to constrain the use of cars. Here, supply and demand both need to be carefully managed to achieve efficiency and, as such, parking policy becomes a key tool for managing mobility and travel demand.

Given the close links between parking and car use, economists and planners see in parking a channel through which they can understand and tackle the challenges of sustainable mobility, improve the quality of life in cities, and promote local economic efficiency. Moreover, the current widespread adoption of parking regulations means parking is seen as a readily available, and more feasible, alternative to road pricing. In short, the Economics of Parking has emerged as a research area that is attracting the growing attention of transportation economists as well as those working in other disciplines, including urban planning and engineering.

The Economic Properties of Parking

Parking is typically classified by economists as a private intermediate good. It can be considered a private good because it possesses the properties of rivalry in consumption and excludability, where rivalry implies competition for the available, but limited, parking spaces and excludability implies the use of pricing and regulations that condition and influence the free choice of road users and parking suppliers. Despite being a private good, public sector intervention is common everywhere, being most intense in urban areas. Such intervention is usually justified by the presence of various market failures, with externalities and imperfect competition being the most frequently discussed in the literature. Interventions usually take the form of (1) public supply of parking spaces both at the curbside and off-street; and (2) regulations affecting the use of parking spaces (who is allowed to park, maximum length of stay, parking fee, etc.) or the available private supply (minimum requirements, garage concessions, quality standards, etc.).

Moreover, parking can be considered an intermediate good because parking their vehicle does not constitute the drivers' ultimate goal. Rather, they park to satisfy other needs and demands—work, shopping, visiting service facilities, leisure activities, going home, etc.—that require mobility from a point of origin to their destination and which are facilitated by the possibility of leaving their car

close to the latter. Thus, any distortion in the parking market will not only have an impact on the transportation sector and its associated externalities but it will also affect the price of almost everything else, including housing, leisure, retail, and firm location among other goods and services, as has been demonstrated and as is described later. Most economic transactions involve transportation, and parking is a compulsory component of that in the case of motor vehicles.

Parking Demand and the Generalized Cost of Transportation

Research into parking demand is extensive but has focused primarily on the impact of curbside parking regulations on commuters' travel choices based on their stated and revealed preferences. Demand is found to vary across time, space, and demand segments, and to be dependent on the relative generalized cost of transportation of motorized mobility, on the one hand, and all other possible mobility alternatives, on the other. Parking is introduced in the generalized cost of transportation by affecting the in-vehicle and out-of-vehicle travel time and its monetary components. Thus, the basic cost function can be generalized to account for parking components in the following manner:

$$\begin{aligned} C_g &= v(t + s) + vw + M \\ M &= \mu + ft + p \end{aligned}$$

where C_g is the full-generalized cost of a private motorized trip, which is a function of three components. First, the in-transit time costs component $v(t + s)$, which depends on the duration of the trip (t) from origin to destination and on the time spent searching for a free parking spot (s). Both are multiplied by the value of time (v). The second component is the time cost out of the vehicle, that is, between the point of origin and the parking space and from that space to the final destination. This component depends on the duration of the walking trip (w) multiplied also by the value of time (v). Finally, the third component is the monetary (out-of-pocket) costs of the journey (M), which includes tolls (μ), consumption of fuel (f), and payments for parking (p). As such, parking is expected to affect all three components of the generalized cost of transportation: it increases the in-vehicle travel costs if the driver needs to search for a free space at destination, which will depend on supply–demand interaction for parking; it increases the out-of-vehicle time costs if the available parking spaces are located some distance from the origin and/or destination, requiring the driver to walk; and it increases the monetary costs of the private journey if parking is not free and a fee has to be paid to park the vehicle. This amount depends on the hourly rate and the length of stay.

Empirical evidence confirms that demand for parking is negatively related to fees and its sensitivity depends on user and trip characteristics. Thus, it tends to decrease with income and to increase with the length of stay. It also depends on the purpose of the trip and increases with the availability of alternative modes of transport. Moreover, it is found to depend on the availability of parking at the point of destination and at home, with free workplace spaces acting as a major incentive to drive to work. The literature also shows negative cross-elasticities between garage and curbside parking demand. See [Marsden \(2006\)](#) and [Lehner and Peer \(2019\)](#) for a complete review of the mentioned issues.

Cruising for Parking

The Economics of Parking has paid special attention to analyzing the search externality, that is, cruising for parking. Drivers occupying a parking space impose a search cost on other drivers if the demand for parking is higher than the capacity constraint, which implies a pure deadweight loss as shown in [Fig. 1](#) (case 1). Furthermore, this market distortion is expected to aggravate other negative externalities, such as congestion, fuel consumption, and pollution, due to the longer duration of in-vehicle trips searching for a free space. This can be corrected by fixing a parking fee such that cruising is eliminated, and parking demand is equated to the parking supply capacity constraint (case 2). In this case, the cruising welfare loss is fully converted into parking revenues. If parking pricing is introduced but kept below the efficient price (underpriced), only part of the welfare loss is converted into parking revenue, as some cruising will still occur ([Inci, 2015](#)).

Initial evidence suggests that cruising for parking affects a significant number of trips because of excessive demand and that this might be the case in many urban areas, although specific figures are a source of debate in the parking literature ([Shoup, 2005](#); [Weinberger et al., 2017](#)). Indeed, cruising statistics are difficult to determine, especially because studies use different definitions and employ different methods of measurement. This is a matter, however, that will attract much attention in the future if attempts at implementing optimal pricing are to be made. The methods traditionally used for measuring cruising can be grouped into three categories: (1) observational methods, including observing cars in the traffic flow and even following them, a method that has recently incorporated GPS technologies; (2) interviews and declared cruising, a method based on asking drivers about their cruising experience; and (3) park and visit tests. Recently, new methods have been adopted to measure cruising that avoid the main shortcoming of these traditional methods: namely, that they are labor-intensive, time-consuming, expensive, and hard to replicate. They include statistical methods involving the automated observation—employing street camera recordings—of cars that pass free spaces, which allows estimates to be made of the share of traffic that is cruising based on geometric probability distributions ([Hampshire and Shoup, 2018](#)). This approach represents a quick, cheap, and approximate method to measure cruising. Alternative approaches include transaction data methods, which use the information collected by parking management authorities to estimate cruising by relating parking space occupancy ratios and the parking rate (number of cars parking per unit of time). The evidence

Figure 1 Welfare implications of cruising for parking and its correction through parking pricing.

suggests that the parking rate diminishes with occupancy ratios, and shows that it falls significantly with occupancy ratios close to 85%. These methods have huge potential, especially given the future availability of data collected using technologically advanced information systems.

The recent literature has also shown an interest in obtaining empirical estimates of the external costs of cruising. Although scarce, some studies provide estimates of these external costs for city residents. [van Ommeren et al. \(2011\)](#) report it to be about 1€ per day in Amsterdam; while [Inci et al. \(2017\)](#) find that the additional time visitors spend searching for each hour a driver stays parked is valued at about 15% of the average wage rate in Istanbul, which is of the same order of magnitude as the congestion costs experienced in transit from origin to destination in the city. To date, little is known about the external costs of cruising associated with raised levels of emissions during the search for a parking space and with traffic congestion. It is hoped that future research can fill this gap.

Market Power, Spatial Competition, and Information Frictions

Cruising is associated with curbside parking, but the parking market also includes off-street garages. Both goods serve the same purpose as non-perfect substitutes; thus, they have different characteristics and one might be preferred to the other depending on the specific context.^a Generally speaking, curbside parking tends to be spread more ubiquitously across a city, while public-access garages are discretely spaced due to construction scale economies. This, and drivers' walking costs to their final destination, gives garages a certain degree of localized market power.

Spatial competition models show that equilibrium in the parking market is reached when the full cost of parking at the curbside and in a garage are equated, adjusting for the variation in cruising times in the case of curbside parking (i.e., [Arnott, 2006](#); [Inci and Lindsey, 2015](#)). When garage prices are higher than those at the curbside, it makes the latter the preferred option and shifts demand to the curb while increasing cruising times. The interplay between the two means garage operators may be able to exploit their market power and take advantage of curbside congestion to charge higher markups.

The general assumption is that the higher the number of competing garages, the lower their prices will fall. However, the few empirical studies conducted to date suggest that they compete little with one other. In contrast, competition is much more intense with the curbside and a garage's dominant position in the area allows it to further exploit its localized market power.^b Additionally, recent evidence suggests that drivers might not be fully aware of the available parking alternatives and their characteristics, which introduce information frictions in the market. Drivers' knowledge in this respect seems to rely on their previous experience. Garages may have certain incentives to engage in the obfuscation of prices (complex and poorly displayed price schedules), so they can further exploit the drivers' lack of knowledge to charge higher prices and so take advantage of their localized market power and the drivers' costly search ([Albalade and Gragera, 2018](#)). The existence of this market distortion may be inferred from the recent boom in

^a Available empirical evidence suggests that curbside parking is preferred in the EU ([Kobus et al., 2013](#); [Gragera and Albalade, 2016](#)), but this can vary depending on garage facilities, safety, weather conditions, etc.

^b Most of these studies focus on the impact of mergers on garage prices, with one exception that includes the impact of curbside parking regulations on garage prices. See [Albalade and Gragera \(2017\)](#) for further description of this topic.

parking information platforms. The complex interaction between these parking market distortions remains an under-researched area requiring further study.

The Interplay Between Parking and Other Markets

As an intermediate good, the price of parking has an impact on the transport sector as a whole and on its externalities. Yet, it also means that its price affects the price of virtually any other good, given that any distortions in this market are transferred to other markets as negative welfare consequences.

When shopping malls provide free parking, they embed the parking costs in the stores' rents and they, in turn, transfer them to their retail prices. It is rational for them to use parking as a loss leader to attract customers into their facilities, and it is rationally used as insurance by shoppers who run the risk of not finding what they were looking for when visiting the mall (Ersoy et al., 2016). Downtown retailers may attempt to adopt similar strategies but with greater difficulties due to higher parking costs (parking regulation). Thus, they frequently lobby for lower parking fees to counter their being accessibility disadvantage vis-à-vis suburban shopping malls.

Likewise, many employers also provide their employees with free parking instead of paying them higher wages. This is mainly due to the tax advantages associated with fringe benefits, which reduce employers' labor costs, and to minimum parking requirements (MPRs), which ensure an abundant supply of parking. This means that employees pay less for parking than the resource costs inducing a welfare loss. van Ommeren and Wentink (2012) suggest that this loss is about 10% of parking resource costs attributable to distortionary fringe benefits taxation plus an additional 18% due to MPRs. These figures do not take into account additional welfare losses, such as those derived from higher congestion, energy consumption, and pollution resulting from encouraging workers to commute by car.

Housing prices are more or less transparently affected by on-site parking. MPRs impose construction costs on developers, which are in turn embedded into property prices, as they tend to bundle parking spaces with properties. Gabbe and Pierce (2017) suggest that the price of bundled units is 13% higher (with rents being about 17% higher) with an estimated deadweight loss for carless renters of about \$440 million per year. The relation between curbside parking and housing prices might be less apparent but is, nevertheless, relevant. If residents enjoy free curbside parking, its cost should be embedded in the property price as an amenity (given that they can use it as their own garage). Bakis et al. (2019) suggest that when the public authorities introduced paid parking this cost was unbundled from property prices, with average housing prices per square meter falling 9%. This link is also supported by evidence from Amsterdam, where the cost of waiting for parking permits (waiting list) is capitalized into housing prices. Here, estimates suggest that residents are willing to pay about 10€ per day for a parking permit (de Groote et al., 2016).

Parking Regulation and Its Political Economy

Most conventional approaches to parking policy interventions are undertaken by policymakers in the belief that it is an infrastructure that should be provided on-site to meet demand and so as to avoid any spillovers into neighboring areas (Barter, 2015). The tendency is to assume that private initiative alone will not provide an adequate supply to meet prospective demand and so impose MPRs, which also result in the private sector facilitating low-cost parking (firms for their employees, shopping malls for their customers, etc.). The unfeasibility of ever-expanding supply in areas of high demand has shifted the focus of intervention to using parking as a travel demand management measure in what has become known as an "area management approach." Taking this approach, cities have tended to keep parking prices low—lower than their social cost—and have focused on the expansion of off-street garages, while introducing controlled parking zones with different types of dedicated curbside spaces, with a clear bias toward residential permits (i.e., mixed use or resident-exclusive, rather than commercial spaces). Besides the introduction of parking pricing, many cities apply maximum stay limits. This is done to discourage long visits; yet, if limits are too lax they do not provide much cruising relief, and if too strict can cause capacity underutilization.

Policymakers take this approach in the belief that reducing the accessibility of cars might hamper the economic vitality of city centers and, at the same time, they seek to minimize political opposition to the implementation of the policy. Evidence in this field has shown that free or low-cost parking and conventional policies have a high cost for society. They encourage excessive car travel demand, impose major externalities (including cruising), and consume too much scarce urban space. This has generated support for the adoption of a "market-oriented" approach, where both supply and demand are managed in order to achieve efficiency.

Several studies have suggested different policy interventions to solve the common-property resource problem and to achieve full efficiency or, at least, to induce welfare gains. There seems to be a consensus on the need to price curbside parking appropriately so as to prevent both cruising and capacity underutilization (Russo et al., 2019). This might be achieved by setting prices at a level that ensures some parking spaces are available at all times, thus eliminating cruising. This needs to take into account garage fees, since increasing the fee differential in favor of garage parking will push drivers to cruise for curbside spaces.^c This is backed up empirically,

^c As long as curbside and garage parking are found not to be perfect substitutes, the differential between the two should be such that the perceived cost is equated. Studies suggest that this can be attained by regulating the price differential between garage and curbside parking, differentiated hourly curbside parking fees, and time-varying or uniform curbside parking fees depending on the restrictions to be faced. See Inci (2015) for further description.

as cities with curbside regulated parking spaces and a proper fee differential with respect to garages report almost no cruising levels. The right pricing also needs to take into account the variation in demand levels over time, leading to the use of dynamic or “performance-based” pricing (as implemented in cities such as San Francisco with its SFpark system).

Other studies show that it is equally important to price residential parking correctly, as the subsidy introduced by residential parking permits has a relevant negative welfare impact. MPRs in new building projects should be removed to avoid overprovision of parking at the expense of higher housing prices. Employer-paid parking is also a relevant issue, since it is a major determinant of employees’ choice of commuting mode. It has been suggested that income taxation exemptions be eliminated and schemes set up to promote alternative transport modes, either using cash-out schemes (allowing workers to choose between free parking or the parking subsidy in cash) or by taxing companies offering parking to their employees (Shoup, 2018).

Although several cities are moving in this direction, many still seem reluctant to adopt a “market-oriented” approach. The theoretical literature suggests that electoral competition and lobbying by interest groups (i.e., residents, retailers, or motorist associations) may explain why policymakers set parking fees too low and offer parking benefits to certain groups. Residents tend to lobby for higher parking fees for visitors, while policymakers are willing to provide them with parking benefits (residential permits) in order to win their electoral support. However, if parking prices negatively affect urban shops, which is a negative externality for residents, then there are incentives for them to team up with retailers to lobby for lower fees (de Borger and Russo, 2017). Parking is both a relevant source of revenue and a major investment in many cities, which means the political economy and institutional setting of parking policies will continue to attract the attention of researchers in the field.

Economic efficiency has centered most efforts when addressing parking issues but equity is also relevant from a policy perspective. Very few studies have focused their attention on equity, providing only weak evidence as to the fairness of paid parking for low-income groups. Chatman and Manville (2018) analyzed the SFpark project and found that the change in parking meter rates did not change the socioeconomic composition of curbside parkers, providing weak support for arguments that market-based fees price them out. In any case, it would be possible to use the parking revenues raised to compensate those negatively affected and, in this way, achieve a fairer outcome if needed. The relevance of this question clearly points to the need for further research.

Parking and Long-Term Decisions

Parking can also be expected to affect households’ long-term decisions—such as owning a car, choosing a residence or a job, or where to locate a firm—given that transport is known to enter the consumers’ trade-off when making such decisions. Research suggests that both owning a car and parking conditions are key elements of households’ travel decisions. If finding an empty space for your car proves costly, it makes it less attractive to own a vehicle, reinforcing parking regulation incentives toward a less car-dependent lifestyle; however, this link is still under researched. To date, only a few papers have examined this link, tending to focus on the impact of parking supply on car ownership. All of them suggest that parking availability increases motorization levels, regardless of whether they focus on free parking supply, parking norms, or residential permits. Guo (2013), for instance, reports that parking supply variables can have more than twice the impact of income on car ownership, depending on the household ownership level. However, there is not yet enough evidence on the impact of paid parking, dedicated spaces with distinct priorities being given to different consumer groups (visitors or residents) that compete for the same parking space, and specific parking regulations (fees, time limits, operating hours, etc.). Some initial evidence suggests that different types of dedicated space have different impacts on car ownership due to the way in which the allocation of parking rights facilitates competition between different demand segments for the same parking spots. As for residence location, it has been theoretically suggested that such a link exists and is relevant (Franco, 2017), but no empirical evidence is available yet.

Technology and Parking Innovations

Current technology has allowed the development of new business models in the parking market that monetize a solution for the inefficiencies discussed earlier but which are quite disruptive in what is still a traditional parking sector.

Space reservation systems have targeted both garage operators and municipalities to offer easy-to-find and quick-to-access parking spaces. The use of sensing technology allows drivers to obtain real-time data on occupancy levels while offering both guidance to parkers and the optimization of parking warden resource allocation.

Online transaction brokers are intermediaries that facilitate parking search and contract (reservation) through a single platform for a commission, as in the hotel and air transport industries. This can potentially generate additional services for both customers and parking operators through the use of gathered information on demand and supply availability. They will not only save drivers time but provide the public authorities with valuable information on how to regulate the market, and offer benefits to other stakeholders (including retailers and car manufacturers) that have a close relation with this market. In this same line, information-gathering platforms, which can also act as transaction brokers, seek to reduce drivers’ search costs in a market where search is costly.

The high sunk costs of garage parking are an incentive for owners to make the most of underutilized supply, especially when urban space is scarce and its conversion to other uses is quite limited. This has led to the emergence of “virtual” garage operators, whose business model is to condition and manage the facilities of others as public-access garages. This has led hotels and retailers to

open up their formerly private-access facilities to the public. In a few cities, some companies have gone even further and have set up parking facility networks that also open up residential private-access garages to the public.

Innovative technology-based parking management solutions are already an important niche of smart city industrial sectors. Smartphones, geolocation, and parking space sensing allow companies to set up innovative business models and encourage cities to implement integral parking management systems that help monitor occupancy levels, make payment seamless, and facilitate regulation enforcement. The capabilities that information technology systems bring to the table in terms of expanding regulatory flexibility and curbing provision costs should help the parking market reach a more efficient outcome and opens up interesting new research questions in the field. All these new systems and business models offer attractive features for addressing market distortions by fostering competition, easing information frictions, and reducing search costs, but researchers have only just started to focus on them and further development is needed.

Microeconomic Theory

The marginal value of travel time (VTT), that is, the money equivalent per minute of travel time, is often said to be the most important number in transport economics, and its estimation has therefore been the topic of extensive academic and applied work. A substantial theory has been developed by economists (e.g. Jara-Díaz and Astroza, 2013) in which consumers are represented as optimising their utility subject to budget constraints on both time and money. This theory allows us to make the fundamental claim that time can have value, being a constrained resource like money. Further, it underpins the calculation of money amounts that would leave consumers in principle indifferent between transport policy scenarios that imply different levels of time expenditure, providing monetary adjustments are also made. This theory and these calculations are the basis for the appraisal of transport projects and policies that change travel times, giving equivalent monetary amounts that are widely used to indicate whether a proposed policy is advantageous to society as a whole.

The VTT appearing in this theory has two components. One relates to the overall time budget that we all face, 24 hours per day. If time spent travelling is reduced, time becomes available for other activities. The second component relates to the specific activity required for travel and is different, for example, between driving a car and waiting for a bus. The existence of this second component means that the specific travel activity must always be considered in stating VTT. We also see that, unlike money, time cannot be stored or borrowed, it must immediately be transferred to another activity, so that the VTT is always measured relative to the next-best activity; this property implies interpersonal variation in VTT, as the next-best activity will naturally vary between individuals.

It is important to note that in the microeconomic theory of consumer behaviour VTT is implied by an equilibrium optimum chosen by consumers in their own current circumstances, that is, this theory does not relate to the history of changes experienced by an individual. The value can vary with the *total* amounts of time and money expended by an individual, for example, as the constraints bind more or less stringently, but the notion of *change* is not relevant to determining the value, according to microeconomic theory, which describes static optimum behaviour. Therefore, in the primary application of VTT, the economic appraisal of transport projects, a single value is required, which will vary between the types of travel activity (driving, walking, etc.) and may vary between individuals, but is independent of the history of changes to the transport system.

Similarly, in the secondary use of VTT, which is to calculate generalised cost or similar time–cost composites for use in demand forecasting, the notion of change does not enter the discussion. The theory here is that each alternative (mode, destination, etc.) has a utility (negative generalised cost) composed of time and cost, brought to a common scale by the VTT. But there is no dependence of utility on previous situations, so that the notion of change is again irrelevant.

Thus, the theories on which the use of VTT are based, both for appraisal and for forecasting behaviour, require a single value for each context, independent of the consumer's history, and therefore issues of sign or size do not arise. However, when methods for measuring VTT are considered, these issues can enter the discussion.

Measurement Methods

While it indicates how VTT is to be used, the theory of time value does not indicate how empirical values are to be obtained. Historically, three approaches that have been used are as follows.

- Models can be estimated from observed (or reported) behaviour and the ratio of time and cost coefficients in those models interpreted as the value of time. Inferring VTT from revealed preferences in this way was perhaps the earliest approach for estimating values of time and corresponds to a classical economist's approach to deriving implicit values from observed behaviour in the marketplace. Here, the notion of change is not directly relevant; the models predict demand based on current travel times and costs without reference to previous times and costs.

- The cost savings approach (CSA) is applicable to time spent travelling by people in the course of their employment, such as plumbers or business representatives travelling to a distant place of work, or professional drivers. CSA then calculates the wage and additional costs incurred by the employer per minute and attributes this as the value of time. Marginal CSA values are independent of the amount of time spent and do not vary by the type of travel activity. Variants of CSA, little used but more sophisticated, such as the Hensher formula, allow for employee productivity en route and for impacts on the individual as well as the employer.
- Willingness to pay (WTP) can be estimated from travellers' stated preferences, most often implemented in the form of stated choices (SC). This approach presents each of a sample of respondents with a series of choice sets, constructed by an experimental design, and from their hypothetical choices estimates of the relative preferences for time and money are inferred. Because surveys of this type almost always present scenarios that relate closely to an actual trip made by the respondent, to preserve realism, the notion arises of *change* relative to that observed trip, often called the reference trip. In the modelling analysis of data of this type, the *sign* and *size* of this change are often found to be relevant to the value that is estimated. In current practice, the SC has come to be the most widely applied approach to estimate the VTT outside of working hours.

Thus, the importance of changes as an influence on behaviour arises only in the context of SC data, but, because of the dominance of SC in practical estimations of travel time value, the issue of the size and sign of time changes becomes relevant and, in fact, important.

For example, in the appraisal of typical transport projects, particularly for road schemes, it is often the case that a substantial part of the value difference between the proposed scheme and an alternative (e.g. 'do minimum') is made up of large numbers of people whose trips would differ in time between the scenarios by small amounts of time, often measured in seconds (e.g. as shown by [Welch and Williams, 1997](#)). When SC data are analysed, provided that the estimation process is sufficiently detailed and the data adequate, values are often found that depend on the size of the time differences being valued: specifically, small time differences are given a lower value (per minute) than larger time differences. Because of the importance in practice of small time differences, the divergence of SC results from microeconomic theory could have substantial relevance for transport policy.

Similarly, it is frequently found that losses of time, that is, increases in journey time, are valued more highly per minute in SC data than gains in time. Because transport policy aims to reduce travel time, the suggestion that time reductions could have a lower value could have important policy implications.

Clearly, the emergence of value differences by the size and size of change is awkward to reconcile with the microeconomic theory. It also presents issues for the process of appraising transport projects. For example, if a project could be implemented in two stages, each giving part of the time reductions relative to a base case, this should surely give the same total benefit as implementing the whole project, but if VTT depends on the size of time saving this will not be the case. Similarly, a temporary change in travel time which is exactly reversed should not have a long-term impact, but if VTT depends on the sign of the time change there will be a permanent loss, as the gain value will be more than outweighed by the loss value.

Essentially, the microeconomic theory and practical logic are at odds with the psychological theory that seems to be needed to explain how travellers respond to SC surveys. This article now continues to discuss these findings, how they might relate to the processes used to estimate the values and what governments have done to resolve the issues that the results raise. First we deal with the impact of the sign of time differences, then the issue of their size, followed by the approaches that have been used to resolve the issues.

The Sign of Time Differences

It is a common observation of human behaviour that people are more upset about a loss than they are happy about an equivalent gain. Politicians appear to be well aware of this effect, which is related to the concept of endowment: 'what I have I hold.' In behavioural analysis, the effect is known as loss aversion and it is an important component of Prospect Theory. There is no doubt that loss aversion is a feature of human behaviour in many contexts.

In the estimation of VTT, WTP implies paying for time, that is, a loss of money equivalent to a gain (saving) in time. In contrast, willingness to accept (WTA) implies a gain of money to compensate a loss in time. Any loss aversion relating to time or money, if it exists in this context, will imply $WTP < WTA$. For example, if there is loss aversion relating to time, then, for a given amount of time loss, the money needed as compensation (WTA) would have to be more than the money that would need to be paid (WTP) for a gain of the same amount of time. A similar argument applies to loss aversion relating to money and, more strongly, if there is loss aversion in both time and money.

The empirical evidence for loss aversion in the estimation of time values from SC data is quite strong. Typically, the monetary value of a loss (WTA) could be 50% higher than the monetary value of a gain (WTP) of the same amount of time, or more when loss aversion is found to apply to both time and money, and the statistics generally indicate that the difference is significant. Since the effect is clearly present in many SC data sets, analysing SC data without at least testing for loss aversion risks biasing other parameters in the model. The methods for making these tests are relatively straightforward.

A more difficult issue is how the effect should be handled in deriving VTT for practical use. When used in forecasting, the notion of change does not apply, since travellers will experience many changes in travel time between their current journey pattern and the

future year for which forecasts are made. They may also move home, leave school, get new jobs, etc., so that the travel pattern is completely different and a reference trip does not exist. Moreover, a fixed value is needed for all units of time, to be consistent with the microeconomic theory. The VTT for gain and for loss must somehow be reduced to a single value.

The solution that has been adopted in practice is to assume that there is some 'underlying' VTT, representing the traveller's long-term preferences, and that the gain and loss values are distorted by the elicitation process or perhaps are short-term effects only. The value that should be used in practice would then be some sort of average of the gain and loss values; typically the geometric mean is used, though the reason for preferring this to other averages (e.g. the arithmetic mean) is purely that it is more convenient in the models (De Borger and Fosgerau, 2008; Hess et al., 2017). Note that this averaging after model estimation is clearly preferable to simply estimating a single value that applies to both gains and losses, because of the potential for distortion of other parameters of the model; additionally, estimating a single value depends on the assumption that losses and gains are balanced in the data.

In summary it can be said that sign differences in time values usually exist in SC data, that they are almost certainly caused by loss aversion, which is itself well established in many contexts, they need to be represented in models estimating VTT and that they have to be handled in practice by some sort of posterior averaging of the gain and loss values.

The Size of Time Differences

Because of the importance of small time differences for many journeys between forecast scenarios, concern is raised by the common finding in analysis of SC data that small time differences, for example under 5 minutes or under 3 minutes, are relatively less highly valued or even not valued at all. The questions that are then raised include the following:

- How can such an effect be brought about?
- Does it depend on the estimation or elicitation methods?
- Is it a component of long-term traveller preferences?

In considering the possible cause of the size effect, it is relevant to think how people think about differences in time or money between alternatives. The standard assumption made by modellers is that they compare the time difference in minutes with the money difference in currency units. But it is also reasonable to consider the alternative assumption that they compare proportional differences and would prefer, for example, a 20% gain in time to a 10% loss in money. Such thinking would obviously be relevant to the comparison of small differences with large ones for trips of a given length, but it does not explain why VTT is often estimated to be less per minute for small time differences.

A possible explanation is given by the different nature of time and money. Presented with a small gain or loss in money, respondents may be able to think of this as an adjustment to their current stock of loose change and therefore to have a moderate value; however, being given a small amount of extra time may have little value, while a loss of a small amount of time may be relatively easy to accommodate, given existing plans for the day. If these mechanisms operated, it would indeed be the case that small time differences had lower value per minute, but perhaps only in the short term.

Another interpretation of the effect would be that the marginal value of time or money increases as the ultimate budget becomes more dominant. The VTT in money terms would then increase as the amount of time and money increase, as is observed, provided that the time budget was more restrictive than the money budget. Large changes in time or money would bring the respective budget limit closer. This explanation would operate in the long term as well as in the short term, providing that the relative stringency of the budgets remains unchanged. However, the empirical evidence argues against this explanation, as the marginal value of both time and cost appears to diminish as the amounts increase.

In summary it seems that we do not have a good intuitive explanation of the size effect. Perhaps respondents are simply indifferent to small amounts of time but willing to attach value to small amounts of money.

The evidence for lower values for small time differences is largely drawn from studies with relatively few observations of such differences, with little variation in the size of small time differences and with relatively simple SC experiments. These are the characteristics of the early SC studies of VTT, where experimental design was not so well developed and on-line interviewing was not possible. In many cases paper survey forms had to be pre-printed with time and money differences presented relative to the reference trip. More recent studies have been able to use more variation in the characteristics of the alternatives presented, with more focus on smaller time differences but without explicit use of the reference trip, and it appears that these changes have reduced the value-per-minute gap between small and larger time differences.

If a reduced value for small time differences is suspected in SC data, this can be investigated by estimating a separate value for each time difference: 1 minutes, 2 minutes, etc. This approach, which was used in a number of early VTT studies, gives the maximum flexibility to determine how the values for small time differences vary, but may not give stable results when the amount of data is small for some time differences. An alternative approach is to postulate a simple functional form, such as that the VTT depends on a power function of the time difference, and estimate the parameters of that function. The latter approach, used in some recent studies following the Danish example, gives more reliable parameter estimates but may miss detailed variations in value.

Because there is no clear intuitive explanation of the size effect, it is difficult to argue that it could be a component of long-term preferences. Some of the proposed explanations imply that it would be a short-term effect or even something provoked by the SC

context. It can be concluded that at present the size effect is not believed to be part of long-term preferences; it would in any case be difficult to see how it could function over the longer term, with shifting reference points.

A complication in connection with the size effect arises when the scenarios presented in the SC experiment have time, cost, or both equal to those of the reference trip. If account is taken of these cases in the modelling, it is often found that the current trip (often called 'as now') is more attractive than would naïvely be expected. Suppressing the effect in the model when it is significant in the data will cause the size effect to be overstated for time and/or for cost, so that the impact on the estimated VTT could be a bias in either direction. Other parameters might also be biased by this omission.

Whatever the fundamental cause of the size effect, it has been observed in a number of SC studies. As with the sign effect, it is therefore necessary to allow for the possibility of size effects (and 'as-now' impacts) in the analysis of SC data (e.g. as in [De Borger and Fosgerau, 2008](#); [Hess et al., 2017](#)). The effects are not always present, but whether or not they will be found in any given data set cannot be predicted without further research. It is possible that more sophisticated designs, for example, with more numerous time attributes, can avoid sign effects and there is some empirical evidence of this.

As with the sign effect, when a size effect is found in SC data a decision needs to be made about how to calculate a value of time for use in appraisal. The key decision is then what time difference should be used to give the representative VTT. Given the small time differences often arising in practical scenario appraisals, it might seem that the values indicated by small time differences might be preferred. However, governments have been reluctant to do this, because the value obtained from these small differences appear much smaller than those obtained from other estimation methods. Moreover, the values associated with small time differences often have rather wide confidence limits, depending on the estimation procedure used, which might undermine confidence in appraisals. Accordingly, an arbitrary decision has usually been taken to use the value associated with a specific moderate time difference, often 10 minutes. This choice is clearly very arbitrary and cannot be described as satisfactory. Governments are however reassured by the fact that this calculation is consistent with past work and with the procedure adopted by other governments.

The Use of Time Values

The estimation of VTT from the analysis of SC data usually gives rise to a sign effect, where losses are valued more highly than gains, and sometimes to a size effect, where small time differences are valued less than moderate or large differences. Other estimation methods, CSA or inference from revealed preference data, do not give these differences. To use VTT, however, a single value is required for consistency with economic theory and because otherwise anomalies can be created in which, for example, the separate benefits of parts of projects do not add up to the total benefit of the project.

It is necessary to include sign and size effects in the model used for estimating VTT from SC data, to avoid biasing the other parameters. However, this implies that a method must be applied for obtaining a best overall estimate of VTT from models that include sign and size effects. In this process, the size effect is considerably more difficult than the sign effect.

- The sign effect is explicable in terms of well-established loss aversion and it seems clear and generally acceptable that an average of gain and loss values can be used.
- No satisfactory intuitive explanation for the size effect seems to exist. To solve the problems it raises, most governments have chosen an arbitrary time difference, usually 10 minutes. Note that it is not reasonable to take the average of the time differences presented in the SC survey, as this would leave the VTT dependent on the survey design, though it would be possible to use the average of several arbitrary time differences. Several governments (e.g. Canada and Germany) have attributed lower value to small time differences in project appraisals and others (e.g. the United Kingdom and EU) have required reporting of small differences ([Daly et al., 2014](#)), although these governments may now have dropped this approach. But all of these approaches are unsatisfactory, as long as the basis for the size effect is not understood.

For short-term projects, an appraisal based on the changes to be experienced by travellers may be acceptable, but here there are also difficulties and these are not the key projects for which VTT is required.

The fundamental issue is that the economic theory required for appraisal excludes the behavioural effects that are required to explain the responses to SC surveys. For the future the options are to try to improve the presentation and analysis of SC surveys or to take a completely different approach to VTT estimation, such as the analysis of revealed preference data.

Introduction

Whenever models are applied to make predictions of future behavior the issue of temporal variation of valuations is important. However, it is an issue, which has received less attention from researchers than efforts to develop models best able to explain current behavior. A closely related issue is that monetary valuations of travel time changes are expected to change over time, and different assumptions around that growth can have important impacts for forecasting. Finally, valuations in transport may change due to wider changes, for example, the use of laptops and smart phones may impact on valuations of travel time for long distance rail travelers.

There is an important distinction between cross-sectional variation in behavior and changes in behavior over time. In recent years, many academic studies have focused on developing more complex representations of travel behavior, for example, by better capturing heterogeneity in preferences between individuals or by modeling the impact of underlying variations in attitudes on traveler behavior. However, while these models can provide a more nuanced understanding of current behavior they do not necessarily yield models better able to forecast behavior over time.

To make predictions of future behavior, it is necessary to make assumptions about how the parameters change over time, if at all, and how the population changes over time. It is important to note that many forecasts are made making the implicit assumption that the model parameters are constant over time without reviewing the evidence for that assumption. Another issue for forecasting is that for some valuations, such as the variation of cost sensitivity to income, the cross-sectional elasticity differs from the longitudinal elasticity and this issue needs to be carefully considered in forecasting.

The issue of population forecasting is important when applying models, if a model incorporates segmentation of behavior across a particular variable then to apply that model there is a need to forecast the future distribution of that variable in the population. This issue is not the focus of this chapter but it is worth noting that applying more complex model forms may be more problematic because of these issues.

This review gives particular prominence to intertemporal variation in values of time (VOTs). This is because this measure is key to both transport modeling and appraisal, and given this there is considerable evidence on how these valuations vary with time.

The remaining sections of this article discuss the various approaches that can be made to assess temporal variation in valuations and summarize what researchers have found. The next section summarizes the temporal transferability literature where the temporal stability of model parameters is assessed, often by using data collected at different points in time. Next, the use of longitudinal studies, which directly estimate variations in valuations using time series data, is discussed. A number of VOT studies have been repeated over time and these sets of studies provide evidence on temporal variation of valuations. Other evidence also provides information on temporal variation including literature reviews and travel budget theory. The final section summarizes the evidence on temporal variation in valuations and sets out areas where further research would be valuable.

Transferability of Cross-Sectional Models

In the transferability literature valuations for different transport alternatives and the characteristics of those alternatives are expressed by the model parameters. The transferability of a model is its ability to predict behavior in a different context to the estimation context (Koppelman and Wilmot, 1982). Transfers may be spatial, for example, from one city to another, but in this context we are concerned with temporal transfers (i.e., transfers over time) of models within the same spatial area.

Most studies have sought to assess temporal transferability by using data collected at two or more points over time. This approach allows the predictions of a transferred model to be compared to those of a model re-estimated on the transfer data. The success of the transfer is then judged based on how well the transferred model fits the transfer data compared to the same model specification

re-estimated on the transfer data. However, in addition some model transfer studies have assessed changes in the model parameters over time and used this evidence to support or otherwise the hypothesis of temporal stability of valuations.

Many of the early model transfer studies were mode choice studies where the short-term impact of a policy intervention on mode choice was assessed (Fox and Hess, 2010). However, some transport models are applied over much longer forecasting horizons of 20–30 years and over this much longer transfer period model transferability may be less likely. In these contexts assembling consistent data suitable for assessing parameter transferability is a significant challenge. In particular, while similar travel diary surveys may be available from different points in time the availability of consistent highway and public transport network models is often an issue.

In some studies, in the absence of detailed data collected at different points in time researchers have examined the ability of models to predict observed aggregate changes in traveler behavior to make assessments of model transferability, for example Milthorpe (2005). However, in such cases it can be difficult to disentangle errors in the forecast of the model inputs from model transferability issues and furthermore such approaches are better placed to assess overall model transferability rather than the transferability of individual parameters.

Much of the transferability literature dates from the late 1970s and early 1980s when disaggregate models were being applied in transport contexts for the first time. Most studies then were mode choice studies and these were generally support of the hypothesis of model transferability over time, albeit based on relative short time scales of 5 years or less. A noteworthy finding that improving the model specification by adding socioeconomic parameters can yield a more transferable model because it helps identify better estimates of the key level-of-service and cost parameters, see for example Silman (1981).

Some of these studies also allow direct assessment of temporal variation in parameter values. By calculating the percentage change in parameter values in each study it possible to examine how the level of transferability varies between different types of parameter (Fox et al., 2014). This analysis found that the level-of-service (travel time, out-of-vehicle time, interchanges, etc.) and socioeconomic parameters were most transferable and as might be expected the constants were the least transferable parameter group.

Some more recent evidence from transfers over longer periods is available from models of either mode choice or joint mode-destination choice for urban areas. The findings from these studies are generally consistent with the earlier mode choice evidence, finding models are generally transferable over time but that the level of transferability varies substantially with parameter group.

A noteworthy finding from some of these studies was that sensitivities to in-vehicle travel were stable to within $\pm 10\%$ over periods of up to 20 years. Thus, there is evidence that valuations of travel time are stable over the long term. This finding is also important in the context of VOTs, which are probably the key valuation measure in transport modeling. In models that have separate in-vehicle time and cost parameters it suggests that adjusting these parameters for future VOT growth can reasonably be achieved by adjusting the cost parameter alone rather than adjusting both sets of parameters.

Longitudinal Studies

Longitudinal studies use data collected over time to provide direct estimates of how key valuations vary over time, often using model forms that directly estimate elasticity to the dependent variables. Typically such approaches use simpler aggregate models compared to the cross-sectional models used in transferability analysis. Their simpler form means that their data requirements are typically less onerous than those of cross-sectional approaches.

A good example of how longitudinal evidence has been used to supplement cross-sectional models is in establishing relationships between VOTs and incomes. Cost sensitivity valuations would be expected to change over time as real incomes increase. However, researchers have found that cross-sectional income elasticities are often substantially lower than corresponding longitudinal values. As such cross-sectional models estimated using data from a single point in time could not forecast changes in cost sensitivity. If data is collected at two points in time, in principle this could be used to estimate a relationship but cost is a particularly difficult variable to model accurately as factors like parking costs and public transport fares are difficult to precisely identify for a given individual, and further there is often a correlation between cost and travel times variables such that if one is weakly estimated the other parameter strengthens. A final related consideration is that the longitudinal analyses have directly estimated VOT relationships whereas in many cross-sectional models VOTs are implied from the ratio of in-vehicle time and cost parameters.

In the United Kingdom, a hybrid approach has been used whereby a longitudinal meta-analysis has been run using the results from cross-sectional VOT studies undertaken over almost 50 years. The total number of valuations included in the analysis was 1750. The meta-analysis models represented variations in valuations by distance, travel purpose, travel mode, data type (revealed versus stated preference) and other effects. The model identified a highly significant relationship between value of time and GDP per capita with an elasticity of 0.9. The model also provides long-term estimates of the ratios between in-vehicle time and other values included in the dataset including out-of-vehicle components for public transport (Abrantes and Wardman, 2011).

Repeated Cross-Sectional VOT Studies

Given their importance to transport planning national VOT studies are often repeated relatively frequently and therefore provide valuable evidence on intertemporal variation in valuations.

Evidence from Dutch VOT studies conducted in 1988 and 1997 found that increase in VOT due to income growth had been offset by a trend decline in VOT such that the real VOT remained more or less constant between the two periods (Gunn, 2001). The most recent Dutch VOT study undertaken using data collected in 2009 and 2011 also identified real VOTs essentially unchanged from the previous 1997 study. Similar findings were made when 1985 and 1994 the United Kingdom VOT studies were compared, and further when the 1994 results for car were compared to those from smaller 2006 study focused on motorway drivers only (Gunn, 2001). Researchers have suggested that increased use of technology such as mobile phones and laptops may have contributed to these findings. However, in contrast to these findings analysis of the 1994 and 2007 Swedish VOT data for car drivers found that the travel cost parameter had declined in real times while the travel time parameter had remained constant, and as such VOTs had risen due to income growth (Börjesson, 2014).

Together these repeated VOT studies raise the question as to why a number of these studies do not identify real growth in VOT whereas the United Kingdom meta-analysis identified strong growth over time. Further research is needed to understand these different findings, in principle they may still be consistent with assuming cost sensitivity decreases as a function of income if sensitivity to travel times due to technological changes also decrease to a compensating amount. The nature of the travel represented may also be relevant, evidence from cross-sectional models often comes from congested urban areas whereas the VOT studies place a greater emphasis on longer-distance travel that may be more impacted by improvements in comfort and technological changes that enable on-board time to be used more effectively.

Other Evidence

In the UK context, evidence from numerous valuation studies was assembled and then a longitudinal model was fitted to the data to test for parameterize relationships between the valuations and income. Alternatively, a literature review approach could be used to summarize evidence from different studies, make assessments of the quality of evidence available from each study, and then form conclusions as to how the valuations have evolved over time.

A separate strand of evidence comes from travel budget theory. Under travel budget theory, individuals have fixed travel budgets of time and money that limit their consumption of these goods. If these budgets remain constant over time then this would provide evidence for stability of valuations over time.

Researchers have often found that at the aggregate level travel budgets are stable between areas and over time, though at the individual level considerably greater variation is observed (Schafer, 2000). Given that the valuations captured in cross-sectional models represent average preferences for the estimation sample these findings are generally consistent with the finding from mode-destination transferability studies that sensitivities to in-vehicle time are constant over time. It is also worth noting that activity-based models place greater emphasis than traditional modeling approaches on the need to represent individual's scheduling constraints on their travel and activity patterns.

Summary

The issue of temporal variation (or stability) in valuations is key to transport modeling and appraisal but it is an area that has been somewhat neglected by researchers, in part because of the data challenges associated with investigating the issue.

An important finding from the transferability literature is that improving model specification can improve model transferability, and in particular helps ensure more transferable estimates of the key cost and time parameters that are key to the future model predictions. Another important finding, and one that has supporting evidence from VOT and travel budget literature, is that in-vehicle time parameters tend to be more transferable than other model parameters.

The issue of predicting VOT growth can be problematic. In many European countries, predictions of growth in VOT are linked to predicted growth in incomes, and in the United Kingdom, this approach is well evidenced by a large meta-analysis of historical studies. However, a number of repeated VOT studies have observed static or declining VOTs despite income growth.

There are a number of areas where further research would be valuable.

The majority of the transferability literature investigated multinomial or nested logit model forms. It would be valuable for research into more complex model forms that have been prominent in academic studies recently, such as mixed as latent class models. Some limited evidence from an investigation of mode-destination models found mixed logit models to be no more transferable than simpler nested logit models.

The issue of VOT growth over time is one that is worthy of further investigation. In particular, the relative contributions of technological and other changes on VOT need to be better understood as it is possible that these can be controlled for then the underlying VOT would still grow with income.

Introduction

The transportation sector is responsible for a significant share of the world's energy use, and it contributes substantially to carbon emissions and local air pollution. One way to reduce the transport sector's energy consumption and the associated negative external effects is to enforce fuel efficiency standards on vehicle manufacturers; examples include the corporate average fuel efficiency standards in the United States and the weight-based fuel efficiency standards in the EU. However, an often-observed effect of the introduction of more stringent fuel efficiency standards is that as the fuel efficiency of cars improves, car use becomes cheaper, thereby providing an incentive to increase its use. Total fuel use thus responds less than proportionally to changes in fuel efficiency. The *direct rebound effect*, or the *pure rebound effect*, is defined as the deviation from this proportionality (Gillingham, 2014).

In the literature many other types of rebound effects have been distinguished, and the typology used is not always the same, even among specialists. One classification is the following (Gillingham et al., 2013). Apart from the direct rebound effect mentioned earlier, two other microeconomic effects are considered. The *indirect rebound effect* is defined as the increased energy consumption from changes (both substitution and income effects) in the use of other energy-using products than the one where the improvement occurs (e.g., better fuel efficiency leads people to spend less on gasoline, but the money saved may be used to buy an extra plane ticket). An *embodied energy rebound effect* accounts for the energy used to create the energy efficiency improvement. Moreover, several macroeconomic effects have been identified, including a price effect and an economic growth effect. Typically, the alternative types of rebound effects point to phenomena that make the total rebound effect larger than the direct part. It has even been suggested that under particular circumstances the rebound effect may more than fully compensate the initial effect, a possibility referred to as backfiring.

The existence of rebound effects is of course not limited to the car industry, but it has been observed in many other energy-consuming durable goods industries as well. It has first been observed by the economist William Stanley Jevons as early as 1865. He noticed that despite huge improvements in energy efficiency of coal-fired steam engines, the use of coal was actually increasing. The rebound effect was so strong that the energy efficiency improvement "backfired": the cost reductions in fact raised energy use. Based on the evidence reported later, such backfiring has not been observed for fuel efficiency improvements in the car industry.

This paper focuses solely on the direct rebound effect, and the attention is limited to vehicles; unless otherwise noted, our focus is on cars. Better fuel efficiency reduces the per kilometer cost of car use, raising the demand for driving, so that some of the energy savings that would have been realized with unchanged behavior are foregone. This behavioral response reduces the effectiveness of fuel-efficiency improvements. The empirical question therefore is to what extent does improved fuel efficiency raise the demand for kilometers driven and, therefore, reduce the fuel savings that would have been realized at constant traffic levels.

This paper argues that the direct rebound effect for cars is not trivial, so ignoring it implies that the expected benefits associated with better fuel efficiency are overestimated. A significant share of the expected reduction in emissions implied by an increase in fuel efficiency leaks away because of additional driving.

The Direct Rebound Effect

The direct rebound effect associated with an improvement in fuel efficiency for cars follows from the observation that better efficiency reduces the per kilometer cost of driving and, therefore, as long as the price elasticity of the demand for driving is nonzero, it raises the demand for driving. Consider a simple economic framework for the choice of car use by households, conditional on owning a car. Assume that the household cares for a general numeraire consumption good x and for kilometers traveled by car. Denote the demand for kilometers by q , and let the car's fuel efficiency (the distance a car can travel per liter of fuel consumed) be

given by E . Assume for simplicity that the fuel cost is the only variable cost. The fuel cost per kilometer driven is then defined as $P = P^f / E$, where P^f is the price per liter of fuel used. Conditional on owning a car, the consumer's short-run problem of choosing the optimal number of kilometers and optimal spending on other goods is:

$$\max_{x,q} (q, x) \text{ s.t. } x + \frac{P^f}{E} q = I \quad (1)$$

where I is the household's income. For simplicity, we ignore the fixed annual cost of car ownership. Assuming that at the optimum $q > 0$, the short-run optimization problem then gives the demand for kilometers as a function of income and the fuel price per kilometer:

$$q(P, I) = q\left(\frac{P^f}{E}, I\right) \quad (2)$$

Note that specification in Eq. (2) implies the implicit assumption that, in absolute value, the effect of a small change in the fuel price and in the car's fuel efficiency on the demand for kilometers is identical. The rebound effect in the early literature was often estimated under this strong assumption. In that case the rebound effect can be estimated simply by the price elasticity of demand for kilometers (q) with respect to the fuel cost per kilometer (P). To see this, note that fuel consumption (denoted F) is the ratio of the demand for kilometers q and fuel efficiency E , so $F = q(P, I)/E$. Differentiating this equation with respect to E , multiplying by fuel efficiency and dividing by fuel use F , we find after simple algebra:

$$\varepsilon_{F,E} = -(1 + \varepsilon_{q,P}) \quad (3)$$

where the $\varepsilon_{i,j}$ refer to elasticities of variable i with respect to j . It follows from Eq. (3) that an increase in fuel efficiency reduces fuel use less than proportionately if the elasticity of demand with respect to the fuel cost per kilometer $\varepsilon_{q,P}$ is negative. Under the assumptions made, the direct rebound effect is simply the absolute value of this elasticity.

The assumption that the effects of fuel price and fuel efficiency on the demand for kilometers are equal in absolute value has been challenged in the empirical literature. There are several reasons why this might be the case. For example, it could be due to consumers being generally less aware of the precise fuel efficiency of the car they drive than about fuel prices, which they observe regularly. Alternatively, it may be that consumers view fuel price changes as temporary while they believe that fuel efficiency improvements are much less likely to be reversed. Unfortunately, the empirical evidence on the relative importance of fuel price and fuel efficiency changes is mixed. Some studies find that the absolute value of the effect of fuel efficiency is substantially larger than that of the fuel price, but there are a number of papers that report the opposite.

Let us allow for different effects of fuel price and fuel efficiency, so that the demand for kilometers is a function $q(P^f, E, I)$ of the fuel price and fuel efficiency separately. Differentiating the definition of fuel consumption $F = q(P^f, E, I)/E$ with respect to E and rearranging, we then find:

$$\varepsilon_{F,E} = -(1 - \varepsilon_{q,E}). \quad (4)$$

The direct rebound effect is therefore defined as the elasticity of the demand for driving with respect to a change in fuel efficiency $\varepsilon_{q,E}$. Note, indeed, that $\varepsilon_{q,E} > 0$.

The rebound effect also has important long-run implications for the effect of fuel prices on fuel use and on the demand for kilometers driven. An increase in fuel prices raises the benefits of driving a more fuel-efficient car and makes it more attractive for producers to develop such cars. This suggests that in the long run fuel efficiency is enhanced by rising fuel prices. Although, conditional on fuel efficiency, higher fuel prices reduce the short-run demand for kilometers, in the long run the fuel efficiency improvements that are the consequence of higher fuel prices generate a rebound effect. They reduce the cost per kilometer and counteract the previous effect. The ultimate long-run effect of the higher fuel prices on the number of kilometers driven is therefore less than what would be expected keeping fuel efficiency constant. To illustrate this, using previous definitions it easily follows that:

$$\varepsilon_{q,P^f} = \varepsilon_{q,P^f} \Big|_E + \varepsilon_{q,E} \varepsilon_{E,P^f},$$

where the notation $\varepsilon|_E$ refers to the relevant elasticity at unchanged fuel efficiency. The overall fuel price effect on demand is the initial effect at unchanged fuel efficiency plus a correction term, reflecting that higher fuel prices raise fuel efficiency that in turn increase demand for kilometers. A similar reasoning implies that the long-run fuel savings of a fuel price increase are smaller than the savings at constant demand for kilometers. One finds, using similar derivations and Eq. (4):

$$\varepsilon_{F,P^f} = \varepsilon_{F,P^f} \Big|_E - \varepsilon_{E,P^f} (1 - \varepsilon_{q,E}).$$

The first term on the right-hand side is the short-run effect at given fuel efficiency. The second term captures the additional effect when people switch to more fuel-efficient cars; this effect is reduced, however, by the rebound effect that induces more kilometers to be driven.

How Large is the Direct Rebound Effect?

Empirical estimates of the rebound effect for cars yield a wide variety of estimates, depending on the country and time period considered and the type of data used (aggregate data vs. observations on individual households), and depending on whether studies take a short- or the long-run perspective on the rebound effect. Moreover, results differ according to the empirical specification of the models estimated and the econometric techniques used.

Estimating the Rebound Effect

The early literature often used aggregate time series for one country, or aggregate panel data for states within a country. The most common way to estimate the rebound effect was to look at the effect of the fuel price per kilometer on the demand for kilometers driven. These studies assumed that in absolute value fuel prices and fuel efficiency affect the demand for kilometers equally. As mentioned before, this assumption may not be appropriate. There is evidence that, although many consumers believe gasoline price shocks to be permanent, there is considerable heterogeneity in these beliefs so that, for many consumers, demand will respond differently to changes in fuel prices and in fuel economy.

A number of studies are now available that estimate the demand for kilometers based on individual data. Many of these studies continue to assume (in absolute value) equal responses of consumers to fuel prices and fuel efficiency. Those that do not assume (in absolute value) equal responses of consumers to fuel prices and fuel efficiency typically make other stringent assumptions. For example, they often implicitly assume that fuel efficiency is not correlated with other characteristics of the car, such as engine power or reliability, that affect the consumer's demand for kilometers driven. Not controlling for these observed and unobserved car attributes leads to biased estimates. Indeed, it has been argued that the vehicle design process suggests that these correlations are nonzero and that, if the correlation were negative, the rebound effect is biased downward toward zero.

Another shortcoming of most empirical studies is that they ignore the interaction between multiple cars in a household. One expects that in multivehicle households the relative demand for kilometers driven in the different vehicles to some extent depends on the price of fuel and on their relative fuel efficiency. To see this, consider a household owning two cars. Conditional on car ownership, the household's short-run optimization problem now implies two demand functions for kilometers, one for each car:

$$\begin{aligned} q_1(P_1^f, P_2^f, E_1, E_2, I) \\ q_2(P_1^f, P_2^f, E_1, E_2, I) \end{aligned} \quad (5)$$

If the cars use different fuels, one fuel price can move independently of the other, and an increase in, for example, P_1^f has an impact on the number of kilometers driven by both cars. The impact of P_1^f on q_2 is caused by substitution toward the car that has become relatively cheaper. If the two cars use the same fuel type ($P_1^f = P_2^f$) then economic theory implies that the total number of kilometers driven by the household should decrease in response to an increase in the fuel price, but the household may use the most fuel-efficient car more intensively. There is evidence that when fuel prices increase households indeed to some extent substitute cars of low fuel efficiency by increasing the use of the high fuel efficiency alternative (De Borger et al. 2016b). However, the majority of papers in the literature estimate the rebound effect by treating each vehicle as an independent observation. This ignores substitution between cars and has implications for the rebound effect estimated.

Finally, with very few exceptions existing studies do not account for the cost of the fuel efficiency improvement itself. The efficiency gain is likely associated with an increase in the car's production cost that is not taken into account. Recently, one or two innovative papers have appeared that derive estimates of the rebound effect from particular policies, for example, policies that give consumers incentives to buy more fuel-efficient cars (see, e.g., Small and Van Dender, 2007). The advantage of this approach is that the characteristics of the vehicles bought can be taken into account and that price effects of the fuel efficiency improvement can be captured.

Empirical Estimates of the Rebound Effect

The transport economic literature offers a fair number of estimates of the direct rebound effect for car transport using both aggregate data and individual household data. Both types of empirical studies are of interest. The studies using aggregate data are useful because of the interest of policy-makers for the system-wide rebound effect. Nevertheless, as the phenomenon originates at the level of the individual actors (households), it is also useful to measure the rebound effect using individual household data.

The most influential studies using aggregate panel data for US states estimate the rebound effect in a system of simultaneous equations (demand for car stock, demand for mileage, and demand for fuel efficiency). They estimate the rebound effect at some 5% in the short run and about 20% in the long run (Small and Van Dender, 2007). That is, 5% of the fuel savings implied by an increase in fuel efficiency under the *ceteris paribus* condition is retaken immediately by a change in driver behavior, and in the course of time this increases to over 20%. The inertia of the adjustment process arises because of the lack of knowledge and due to the time needed to adjust planned travel behavior or to expand or contract the vehicle stock. These studies also find that the rebound effect is declining over time, and this phenomenon is attributed to increases in incomes. The income elasticity of car use is usually small and

decreases with income. Extending earlier results using a larger data set and accounting for the potential importance of congestion in explaining the decline in the rebound effect does not drastically affect the conclusions (Hymel et al., 2010). Moreover, some evidence is reported that the rebound effect may be asymmetric: it is larger in periods of fuel price increases than in years when fuel prices decline; most likely this is because drivers are more aware of the fuel costs when the fuel price rises. Lastly, the rebound effect is also greater during times of media attention for fuel price increases and fuel price volatility, for similar reasons.

Many studies based on individual household data have rejected the equality (in absolute value) of the effects of fuel efficiency and fuel prices on the demand for driving. Unfortunately, there is no unanimity on which effect is larger. Some studies find that households respond more strongly to changes in fuel prices than to fuel efficiency changes, but others find the opposite. All suggest, however, that higher fuel prices induce households to switch toward more fuel-efficient cars.

Several studies using individual data for the United States have found rebound effects toward the high end of those reported using aggregate data. An early study based on household data over the period 1979–94 estimated the rebound effect at 17%–28% (Greene et al., 1999). In a very careful analysis based on individual household data for the United States, several of the restrictive implicit assumptions mentioned earlier have been relaxed; the study allows for multiple cars per household, it allows different effects of fuel price and fuel efficiency, and it captures the correlation of improved fuel efficiency and other car attributes. Estimates for the rebound effect were in the range of 20%–40% (Linn, 2016). A study estimating the rebound effect using information on the effect of a real-world policy to induce people to switch to a more fuel efficient car reports an elasticity of driving with respect to the operating cost per mile of -0.15 .

Remarkably, estimates based on European data show much larger variability between different studies. In some countries much higher values have been reported than for the United States. For Germany, for example, values for the rebound effect of up to 60% have been estimated (Sorell et al., 2009). Using Swiss data and accounting for the endogeneity of distance, fuel intensity, and vehicle weight, even higher values of almost 75% were found. However, based on a first difference model for a very large sample of individual household data for Denmark, the most reliable estimate of the rebound effect is much smaller, amounting to some 7.5%–10% (De Borger et al., 2016a). This study finds that the fuel price sensitivity of the demand for kilometers is declining with household income, but it does not confirm earlier suggestions in the literature that the rebound effect decreases with household income. These earlier observations relied on the imposed restriction that households react identically to changes in the cost per kilometer caused by changes in fuel price and fuel efficiency. The Danish evidence suggests that the sensitivity for changes in the fuel price reduces significantly with income, but the direct rebound effect itself is unrelated to income. Formulated differently, the declining rebound effect reported in the previous literature may have been primarily driven by declining sensitivity with respect to fuel prices, whereas the rebound effect may have been more or less constant over time. Simulation results further suggest that the small pure rebound effect and the impact of adaptations in all car attributes jointly imply that higher fuel prices lead to a substantial reduction in both the demand for kilometers and in demand for fuel.

Finally, the recent literature finds important and significant substitution effects between cars within households owning multiple cars. A fuel price increase leads households to drive more in the car with better fuel efficiency and demand for driving the least fuel efficient car declines (De Borger et al., 2016b). As a consequence, elasticities of kilometer demands with respect to fuel prices that are estimated are substantially smaller than the corresponding fuel price elasticities of fuel use. This suggests that higher fuel prices not only stimulate replacing less fuel-efficient cars by more fuel-efficient cars but also in the short-run substituting vehicle use within the household.

Although it is difficult to separate the effect of individual assumptions on estimated parameters, one suspects that not allowing for multiple cars per household and the possibility of substituting between cars leads to overestimating the rebound effect.

Conclusion

Increasing environmental awareness in transport policy-making, concerns of energy security and increasing fuel prices have generated a revival of interest in the economic implications of fuel prices and fuel efficiency policies on car use. The efficiency of policies to reduce fuel consumption (fuel taxes, fuel efficiency standards, etc.) is mitigated by changes in consumer behavior. Higher fuel prices in the long run lead consumers to switch to more fuel-efficient cars. Moreover, improved fuel efficiency reduces the costs of car use, thereby providing an incentive to increase its use. This is the direct rebound effect: the savings in fuel consumption of a 10% improvement in fuel efficiency are less than 10%, because people drive more kilometers. The effectiveness of fuel efficiency policies is critically depending on the magnitude of the rebound effect.

The best estimates in the relevant empirical literature yield on average a direct rebound effect of about 10%–20%, but there is significant variation, especially among studies using European data. The interpretation is simple: 10%–20% of the fuel savings due to improvements in fuel efficiency leak away through additional driving. Earlier studies using aggregate data suggested that the rebound effect was declining over time due to rising incomes. However, recent empirical findings based on individual household data do not confirm this hypothesis. They suggest that the sensitivity of the demand for driving with respect to changes in the fuel price reduces significantly with income, but the direct rebound effect itself does not decrease with household income. Finally, many earlier measurements of the rebound effect may have to be revised to account for the possible substitution between cars in multiple car households.

Analyses of the determinants of fuel use and of the rebound effect are highly relevant for policy. Driving does not decline as much as would be the case in the absence of the rebound effect, and the additional driving due to better fuel efficiency also contributes to

congestion and traffic accident risks. The effects of policies that differentiate fixed car costs on the basis of fuel efficiency—through taxes on new cars or on car ownership—on kilometers driven and pollution are similarly affected by the rebound effect. In general, the rebound effect reduces the net benefits of fuel efficiency improvements, raising the welfare difference between first- and second-best policies. Measurements of the direct rebound effect for car transport can contribute to the ongoing debate on strengthening fuel efficiency standards and the adoption of new technologies such as car sharing platforms, electric vehicles, and autonomous vehicles.

Given its importance and the wide variation in empirical estimates, the size of the rebound effect remains an ongoing debate. Future work might want to include the supply side of the market for new cars and the role of expectations about gasoline prices in estimating the rebound effect. Moreover, with few exceptions the available studies focus on cars. A careful analysis of the rebound effect and fuel price changes in freight transport based on individual firm data, and embedding the rebound effect in general equilibrium models of the energy sector are useful extensions of the available literature.

Why Use Elasticities?

Travel demand elasticities indicate the sensitivity of travel demand to changes in relevant variables like price, journey time, and income (Goodwin, 1992). They are vital to public transport operators, allowing them to make judgments about how changes to their services may impact travel demand. The Passenger Demand Forecasting Handbook (PDFH), for example, explicitly contains price elasticities that are extensively used by the railway industry in Great Britain. They also can inform demand forecasting, investment decisions, and policymaking more generally. Elasticity measures generated from observed changes in travel demand are also used as a measure to validate the sensitivity of travel demand models. In fact, the UK Department for Transport explicitly requires travel demand models developed in the United Kingdom to conform to specific elasticity measures in its modeling guidance, saying “the acceptability of the model’s responses is determined by its demand elasticities (DfT, 2019)”.

Elasticities can also provide evidence on the potential size of induced demand effects from road improvements that increase capacity, although their use in transport appraisal is at an early stage of research. Induced demand for road travel can be broadly defined as “the increment in new vehicle traffic that would not have occurred without the improvement of the network capacity” and affects the benefits estimated for a road project as well as on markets from which traffic is displaced (Dunkerley et al, 2018b).

As well as providing information on demand responses, elasticities are used in the calculation of wider economic impacts of transport projects. For example, the elasticity of productivity with respect to effective density, which measures firms’ access to economic mass, and the elasticity of labor supply with respect to wages are used in UK transport appraisal guidance for the calculation of agglomeration effects and labor market effects, respectively.

What Do We Mean by Elasticities?

Elasticity is a general economic concept, which is used to describe the responsiveness of one variable to changes in another variable. In economics and transport, elasticities are often used to determine the demand response to changes in price, income, or other relevant variables. In this chapter we refer to travel demand elasticities only, although, as noted above, a wider range of elasticities are relevant to the transport sector. These demand elasticities are defined as the percentage change in demand for each percentage change in the variable of interest and are hence unitless. Negative elasticities indicate a negative relationship between demand and the variable of interest; positive elasticities a positive relationship. For example, an own-price demand elasticity of -0.5 means that for each percentage increase in the price of traveling by a mode the total demand for that mode will decrease by half a percent (0.5).

An elasticity value of 1.0 (or -1.0) means that changes in the variable of interest causes proportional travel demand changes. Elasticities with magnitudes less than 1.0, referred to as inelastic systems, mean that the travel demand changes are less than proportional to the change in the variable of interest. Elasticities with magnitudes greater than 1.0, referred to as elastic systems, mean that the travel demand changes are larger than proportional to the change in the variable of interest.

Demand elasticities will be influenced by a number of factors in the transport system, including the type of market (or type of travel), travel alternatives that are available, time periods for action, etc. In general, transport elasticities are expected to increase in magnitude over time, as consumers have more opportunities to adjust behavior, for example, to purchase a car, or change their residential or work location.

Cross elasticities measure the sensitivity of demand for one mode relative to changes in relevant variables like price and journey time for “another mode” (Fearnley et al., 2017). For example, the elasticity of demand for rail (patronage) due to changes in petrol

prices. They represent the percentage change in demand for one mode that results from a 1% change in price on a second mode. Cross elasticities depend strongly on local circumstances, including on the availability of alternative modes. For example, if people have access to a number of modes, you might expect much higher cross elasticities.

Linked with cross elasticities are “diversion factors,” which quantify how changes in one mode impact demand for other modes and for new trips. In transport appraisal they are used to determine the source and extent of new traffic resulting from an investment. For example, a new rail line may draw users from a range of other modes, for example, 30% may come from existing bus services, 40% from car, and maybe 30% will not have made the journey before. The percentages reflect the diversion factors (translated to values between 0 and 1). Note that diversion factors say nothing about the volume of traffic that moves to a mode (a new rail line in this case), only the way it has been reallocated from other modes (including not traveling). Diversion factors are also useful because they allow cross-price elasticities, which are often difficult to determine directly from observed data, to be calculated using (own) price elasticities and relative market shares only.

While diversion factors are a useful, practical tool, they have a number of properties that are important to understand when using them. For clarity, in our work we define an “intervention mode,” that is, the mode where the intervention (e.g., fare, capacity or level of service change) is applied and “recipient/source modes,” that is, the modes that are affected by the change in demand for the intervention mode. The “recipient/source modes” terminology reflects the fact that demand may move to or from these modes depending on the change on the intervention mode, although the diversion factor will be the same in both cases. If the change is positive, for example a bus fare is reduced, the diversion factors represent the proportion of traffic switching to bus from other modes. If the change is negative, for example a bus fare increase, the diversion factor represents the proportion of traffic diverted to other modes from bus. This property can be termed equivalence. A second property of diversion factors is that they are generally not symmetric but depend on which mode is subject to a change. The bus–rail diversion factor resulting from a bus fare increase will not be the same as the bus–rail diversion factor if there was a rail fare rise instead. Finally, diversion factors like elasticities are influenced by context and may depend on trip purpose, availability of other modes, area type, etc., as well as calculation methodology.

How are Elasticities Determined?

Elasticity values are usually obtained from regression models using aggregate time-series data of observed travel demand as well as information on key variables explaining travel demand, including income, car ownership, service levels for the mode of interest and competing modes, etc. A range of approaches are used to account for effects such as endogeneity, where changes in an explanatory variable of interest, such as road capacity, may also result from changes in demand, or the lagged nature of a response. These approaches may lead to differences in estimated elasticities that cannot always be easily explained.

It is important to note that elasticities are not necessarily constant, as they may depend on the average values of the variables over which the changes are measured; for example, sensitivity to travel cost may depend on the amount actually paid. The choice of regression model used to calculate the elasticities determines the relationship between demand and the variable of interest. For example, if a log–log model is used for demand and price, the resulting price elasticity of demand will be constant for all levels of demand. A linear relationship on the other hand would mean that the elasticity would depend on both the average price and average demand. This also has implications for how they are used in demand modeling. If composite terms are used, such as generalized cost, which combines variables into an equivalent monetary amount, or generalized journey time (GJT), which conflates various time related attributes such as in-vehicle, walk and wait into a single time term, then even if the elasticity to the composite term is constant the implied elasticities to the constituent variables will not be constant. So, for example, if generalized cost is used, the implied price (time) elasticity will depend upon the proportion that price (time) forms of generalized cost.

Several research methods have been used in the literature to calculate diversion factors: observed changes in behavior based on survey data, reported best alternative to the mode that is used, stated intentions, for example, what choices travelers might make in new or different situations and transfer time and transfer price questions, for example, the price (or time) change required to change behavior. Most surveys reporting observed changes record the impact of an intervention on a particular mode, by asking users of that mode what mode they previously used. An intervention in this case could be new infrastructure or an improvement to an existing service. The other research methods are based on a second approach that involves asking transport users about potential changes in behavior. These methods determine the behavior change that would occur when a mode is no longer available, or the journey cost or time make it unacceptable to a user. This could be for a number of reasons that are related to interventions, such as closure of infrastructure or reduction of services, fare increases, or other policy measures. Although recent work does not find substantial differences in the diversion factor values across these sources, estimates from real transport changes are preferred.

Meta-analysis is a useful method for combining datasets to explain the variation in elasticities across a range of attributes. It has been applied to price and time elasticities in the transport sector.

Deducing Demand Elasticities

There are sometimes instances where it is beneficial to be able to deduce elasticities for a particular variable from available evidence relating to other variables. The most obvious case is where there is, for whatever reason, no credible evidence for a variable, but there might also be a need for supplementary evidence for benchmarking purposes. Good examples of a dearth of own-elasticity evidence are journey time elasticities for bus and car travel and the access time elasticity for rail travel. Evidence on the former tends to

be scarce since bus and car journey times exhibit relatively little variation over time whilst the models used to estimate rail elasticities tend to be based on station-to-station demand and hence do not cover the access element.

If a unit change in generalized cost has the same impact regardless of whether it stems from a change in price or journey time (or any other variable within generalized cost) then a relationship exists between the own elasticities for price and time (and any other variable within generalized cost). So, for example, the journey time elasticity for a mode can be deduced as the product of its price elasticity, its journey time weighted by the value of time, and the inverse of its price. For access time, we would replace the time elements with the level and value of access time.

A related approach where discrete variables are concerned is to estimate demand impacts from known elasticities using valuation estimates. Generally, there is little evidence on the effects of how rolling stock, information provision, station facilities and a range of such “soft” or “secondary” quality factors impact demand. The approach often adopted is to obtain a valuation of the improvement, typically using stated preference methods, and to treat the improvement as if it were an equivalent reduction in the variable against which the improvement has been valued. Therefore if the valuation indicates that the improvement is equivalent to a 3% reduction in fare, the demand effect is inferred from applying a reference fare elasticity to the 3% fare reduction.

Similarly, there is a relationship between relevant cross and own elasticities, which is useful to deduce cross elasticities where there is a lack of relevant evidence or where there is a need for benchmarking evidence. It can be shown that the cross elasticity of demand for mode i with respect to, say, the price on mode j is the product of the absolute price elasticity on mode j , the ratio of demand for mode j and mode i , and the diversion factor between mode j and mode i as defined above. Such a relationship is also useful because it allows cross elasticities to be customized to the particular application circumstances.

Recent Evidence on Road Traffic Demand Elasticities

In 2014 we undertook a rapid evidence assessment to identify literature evidence for road passenger and freight traffic elasticities with respect to key economic and demographic factors, specifically population growth, income growth and changes in fuel costs (Dunkerley et al., 2014). The main objective of the review was to identify the elasticity estimates that were available in published literature with respect to these variables and, where evidence exists, to explore how these elasticity values have changed over time, if indeed they have changed at all. The evidence review not only focused on UK evidence, but also considered international evidence, particularly if it used UK evidence alongside evidence from other countries. It also focused on studies published after 1990.

In a rapid evidence assessment a range of academic databases is searched in a systematic way using reproducible search terms. The approach differs from a full systematic review, as the literature searched can be limited in terms of language, publication data, and geography. In this case the study was limited to English language, OECD papers from 1990 on. The academic search was complemented by approaches to key contacts and web searches to identify grey literature.

We found that the range of estimated “fuel price elasticity” values was quite narrow (-0.1 to -0.5), although a variety of data types, methodologies, and fuel price definitions (prices in pence per liter or pence per km) were used to obtain elasticity estimates. In the long run, improvements in fuel efficiency will result in a smaller reduction in demand for a given price rise—the so-called rebound effect. This should be reflected in a lower fuel price elasticity. Otherwise, fuel price elasticities will be expected to vary by distance, area type and trip purpose. Price elasticities defined in terms of vehicle kilometers will be larger than those for trips because, as fuel prices vary motorists will alter the kilometers per trip in addition to the number of trips. And in turn the elasticity with respect to the amount of fuel purchased will be larger yet as a result of changes in the efficiency of driving in response to price changes.

For road passenger transport, reported “income elasticity” values were predominantly in the range 0.5 – 1.4 . The evidence indicated that car ownership had a strong, positive, and indirect effect on the income elasticity of demand. Some studies, however, do not include this and only report the direct effect of income on demand. In addition, Gross Domestic Product (GDP), household income, and expenditure are all used as proxies for income. These measures may have different impacts on demand (and elasticity measurement) due to the underlying factors they encompass. For freight transport, elasticity estimates of economic activity are mainly in the range 0.5 – 1.5 for an aggregate commodity sector but there the evidence suggests a much greater variation between sectors. Economic activity is also measured by a number of variables: GDP, GFE, and indices of industrial production.

The evidence on how fuel price elasticities of car demand have changed over time was limited. However, fuel price elasticity is expected to increase with fuel price and decrease with increasing real income, and these impacts could explain the changes observed. There is also limited evidence that income elasticities of car demand have decreased over time: two studies found that elasticity with respect to GDP fell after the year 2000. This could be explained by saturation in car ownership levels. For freight transport, the evidence appears to be mixed.

The study highlighted a number of important gaps in the evidence base:

- First, that much of the evidence on car traffic elasticities for the United Kingdom was rather old. This has implications for the use of elasticities in forecasting and strategic planning because of the mixed evidence on changes in these over time.
- We found no information on population elasticities *per se*. However, a few studies did include demographic explanatory variables, such as urban density, population density, employment, and age, from which it is possible to calculate a corresponding elasticity.
- There has been little investigation of the factors that may be responsible for the decoupling of freight transport and economic activity seen in the 2000s. Although the share of van use increased significantly over the same period, there appears to be no evidence on the impact of this on demand for freight transport.

Evidence on Elasticities of Induced Demand

Elasticities of demand with respect to road capacity expansion provide a measure of the induced demand effect that can easily be derived from econometric analysis. In a recent review, most of the evidence was found to be of this type (Dunkerley et al., 2018b). These econometric studies use observed traffic volumes and nonspecific interventions (increases in lane-km or length of road network) rather than actual responses to particular road building projects. There were not only differences in the geographical scope of the studies and the types of road included but also the approach to controlling for background traffic growth and endogeneity (road capacity may also increase as a result of traffic volumes); these differences may explain the wide range of elasticities reported. Short-run estimates range from 0.03 to 0.6; long run estimates from 0.16 to 1.39.

The elasticity evidence is consistent with the expectation that there are more sources of induced demand in the long run when changes in employment, residential location and land use may play a role than in the short run. Of course, it is not clear whether these changes in employment and residential location are transfers from other areas, which may see reductions in travel.

Studies that differentiate between urban and non-urban areas find a larger induced demand effect in urban areas. Urban areas are expected to have high initial levels of congestion and potentially higher levels of suppressed demand. However, only one study analyses the effect of a metro system on road traffic and finds a much smaller induced demand effect in cities with metro systems.

Induced demand elasticities that are close to one are associated with studies that estimate long-run elasticities for specific road types, particularly in large metropolitan areas, outside of the United Kingdom. They also mainly use the same methodological approach. As they focus on particular road types, the demand response reported in these studies generally include reassignment effects and is larger than the induced demand response.

There is no recent econometric evidence on project level investment. Findings for state level road networks in the United States and the national Dutch network indicate an elasticity of around 0.2 across the whole road network, that is, 10% increase in road capacity could lead to 2% induced demand on the network.

Recent Evidence on Bus Elasticities

In 2017 we undertook a rapid evidence review to identify evidence on bus fare and journey time elasticities and diversion factors for all modes (Dunkerley et al., 2018a). We used a systematic search procedure to identify relevant academic and gray literature through structured database searches, as well as making enquiries to experts in the field to identify material, such as unpublished studies. The study focused on material produced in or that was judged to be relevant to the United Kingdom.

Little recent evidence on bus fare elasticities (in the United Kingdom) was found—and little evidence on bus journey time elasticities generally. A key feature of the bus market in Great Britain is concessionary travel, with nationwide free bus travel available since 2008. The most recent work on bus fare elasticities in 2014 is contained in an extensive meta-analysis of UK evidence on fare elasticities (Wardman, 2014). It covered 1633 elasticities estimated between 1968 and 2010, with 377 (23%) of the observations relating to bus travel. A meta-model was estimated to explain variations in elasticities across studies and found short-run elasticities that strongly support the short-run recommendations of Toner et al. (2010), which is the most recent UK work in the area and took account of the impact of concessionary fares. Long-run commuting and leisure elasticities implied by the meta-model very much support existing official guidance.

The most extensive review of time elasticities ever conducted (Wardman, 2012) uncovered only 16 observations of in-vehicle time (IVT) elasticities. A meta-model estimated as part of that study is used to provide estimated IVT elasticities.

Recommendations for bus fare and journey time elasticities are summarized in Table 1.

Evidence on Rail Elasticities

Rail elasticities are used extensively by the railway industry in Great Britain. Rail demand elasticities for journey time, cost, and income are recommended in the PDFH. Elasticities vary by ticket type, journey type and time period. Table 2 shows illustrative rail price elasticities, again derived from the work of Wardman (2014).

Table 1 Recommended bus fare and journey time elasticities in the United Kingdom

Segment	Time period	Bus fare elasticities		Generalized journey time elasticities
		Urban	London and rural	
Commute	Short run	−0.30	−0.40	−1.15
	Long run	−0.65	−0.85	
Leisure	Short run	−0.40	−0.55	−1.05
	Long run	−0.85	−1.10	
Overall	Long run	−0.7 to −0.9		−1.1

Source: Bus fare elasticities from Wardman (2014) and Generalized journey time elasticities from Dunkerley et al. (2018a)

Table 2 Illustrative rail fare elasticities

Ticket type	Time period	Illustrative rail elasticities				
		Short rail trips			Intercity	
		PTE	London	Other	To/from London	NonLondon
Season tickets	Short run	−0.18	−0.19	−0.31	−0.31	−0.28
	LR	−0.36	−0.38	−0.61	−0.61	−0.57
	PDFH–LR	−0.60	−0.50	−0.70	−0.75	−0.90
Non-season						
First	LR	−0.65	−0.69	−1.10	−1.10	−1.02
Full	LR	−0.70	−0.74	−1.19	−1.19	−1.10
Reduced	LR	−0.94	−0.99	−1.58	−1.58	−1.47

Source: Based on the data from Wardman (2014)

Again evidence on journey time elasticities for rail are provided by Wardman (2012), who collated evidence on elasticities for travel time, GJT and service headway. GJT is a concept widely used in the railway industry in the United Kingdom and is composed of station-to-station journey time, headway, and interchange, with the latter two converted into equivalent units of time. The railway industry's PDFH then recommended GJT elasticities ranging from −0.7 to −1.1 across a wide range of flow effects (but did not provide recommendations for journey time or IVT). The Wardman meta-model indicated that long-run GJT elasticities were larger than those recommendations (0.7 to −1.1) and included a modest but sensible distance effect. The PDFH recommendations were revised on the basis of the metaanalysis evidence. Estimated time elasticities were found to be in the order of 60–75% of the GJT elasticities, and encouragingly this is very much in line with the proportion that journey time typically forms of GJT.

Travel time variability is important to travelers, with studies indicating it to be one of the most important factors for rail travelers. In recent years, there has been much more focus on the direct estimation of elasticities to late time rather than relying on deduced elasticities. The evidence from rail demand models indicates a late time elasticity of around −0.07 for commuting flows into London and −0.10 for such flows elsewhere, with noncommuting elasticities around 20% larger. The elasticity for airport flows is, as might be expected, somewhat larger at around −0.25.

Evidence on Diversion Factors

A substantial database of diversion-factor evidence was identified and collated in the Dunkerley et al.'s (2018a) study. Recommendations are provided based on analysis of the available evidence. In general, we find that the evidence on diversion factors is very diverse, covering a wide range of mainly metropolitan geographies, trip purposes, journey types and alternative transport options (Table 3).

Table 3 Recommended diversion factors in the United Kingdom

Intervention mode	Recipient/source mode					
	Bus	Car	Rail	Light rail/metro	Cycle	Walk
Bus		All trip purposes: 0.20–0.35 Commuter: 0.30–0.55	Urban areas: 0.05–0.2 Intercity: 0.45–0.65	Urban areas: 0.05–0.35	Urban areas: 0.04–0.08	Urban areas: 0.1–0.3 Urban areas: 0.10–0.20 Interurban: 0.07–0.11
Car	Urban areas: 0.20–0.40 Interurban: 0.07–0.11		Urban areas: 0.05–0.20 Interurban: 0.55–0.75	Urban areas: 0.10–0.35	Urban areas: <0.1	Urban areas: 0.05–0.15 Urban areas: 0.1–0.25 Interurban: 0.10–0.25
Rail	Urban areas: 0.25–0.4 Interurban: 0.1–0.2	Urban areas: 0.3–0.45 Interurban: 0.4–0.55		Urban areas: 0.05–0.15	Urban areas: <0.1	Urban areas: <0.05 Urban areas: 0.10–0.20 Interurban: 0.10–0.20
Light rail/metro	Urban areas: 0.25–0.4	Urban areas: 0.15–0.3	Urban areas: 0.15–0.3		Urban areas: <0.1	Urban areas: <0.05 Urban areas: 0.10–0.20
Cycle	0.150.05–0.4, higher for walk and bus					

Source: Based on the data from Dunkerley et al. (2018a)

Some may judge the diversion factor for bus interventions and car users to be high (0.30–0.55). However, we note that first the factor for commuters is higher than for other travelers. Second, the factor only describes the proportion that comes from other modes; therefore for the case of bus interventions, the proportion of the new demand for bus that would come from car is in the range 0.30–0.55. The corresponding demand depends on the baseline share of bus, which usually has a smaller mode share, relative to car and can be determined from cross-price elasticities. Third, there is scope for rebound effects. For example, if there is an intervention on bus that attracts car users, then in theory the road should be less congested, which may attract new car trips back from other modes, including bus (see induced travel discussion earlier). We do not believe that the diversion factors take account of second order effects. This would depend on the timescale over which the data were collected.

Summary

This paper has mainly focused on the United Kingdom both in terms of evidence on elasticities and how they are used in transport. Although quite there is quite a lot of evidence, there are gaps in terms of age of the data (road demand elasticities), geographical relevance (induced demand), or lack of data (time elasticities for bus). While the evidence base for rail is quite strong, this may need to be revisited, particularly for commuting, as working practices evolve.

Introduction

Understanding how parking fees affect mobility is critical for many stakeholders, including urban planners, policy makers, garage owners, and facility managers. A too low parking price stimulates car traffic. It makes car travel attractive due to its low overall cost. It can cause cars to cruise in the hope of finding a free parking space. The share of cruising cars in total traffic was found to be as high as 74% in city centers (Shoup, 2006). Imperfect parking prices can lead to lost revenue, for the car park owner and for local companies that benefit from visitors. Not the vehicles with a high willingness to pay use the parking spaces, but those that are willing to accept long cruises, wait for a free spot or were simply lucky enough to find a free parking space first.

This chapter of the Encyclopedia discusses: the importance of parking price elasticities for designing parking policies, how strong parking fees affect parking demand, and how parking elasticities can be measured and calculated. "Theory" defines parking elasticities and discusses which factor affect them. "Data collection and calculation of elasticities"

shows how to collect data for, and calculate, parking price elasticities. "Empirical values" states and summarizes empirically measured parking price elasticities.

Theory

Every car park, be it an underground garage or on-street parking, has a certain demand structure. The demand structure of a car park is determined above all by the demand for access to the location and the attractiveness of nearby parking spaces, as well as the attractiveness and availability of other access options (Lehner and Peer, 2019). As a general rule, higher parking fees for a given facility reduce demand. Price elasticities indicate the relationship between prices and demand.

Every car owner has to deal with parking decisions. A parking decision is based on where and when a car is parked. It should be noted that not only parking related factors influence parking decisions. If the reasons for a visit to a particular place decline, the need to park there does so too. In addition, the total travel costs of all access options to the final destination influences the parking demand. A vivid example are rural commuters who use Park & Ride at the city border, instead of garages in the city center, to avoid traffic congestion.

Parking price elasticities express the responsiveness of the quantity demanded for parking and the price of that same good. The elasticities are often studied within a specific setting, defined by a shared location, price point and regulation. Regulation objectives, such as parking availability or profit maximization, vary between different settings. Managers often aim to regulate one of the following indicators, while keeping the others in an acceptable range. Parking **volume** is the total number of vehicles using a certain parking facility within a defined period. The point of reference for a parking activity can be the pull-in or pull-out event. Parking **dwelt time** presents how long cars occupy a parking space. **Occupancy** is the ratio between consumed parking and supplied parking. It displays how many parking spaces are in use (or vacant) at a specific point in time or over a period. Occupancy cannot exceed 100% and cannot be lower than 0%. Occupancy is a function of volume and dwell time. Under controlled conditions, the price elasticity of occupancy equals the price elasticity of parking volume and dwell time (Lehner and Peer, 2019). Parking **revenue** is the total income generated by a certain facility within a certain period. Depending on the price structure, revenue is a function of volume and dwell time.

Supply restrictions strongly affect parking elasticities. The costs of parking not only consist of parking fees, but also indirect costs, such as access (additional ways to reach the parking destination), search or queuing and egress (way from the parking to the final destination) time (Axhausen and Polak, 1991). As the direct cost stays constant, the indirect costs grow in relation at high occupancy levels. Parking demand cannot exceed parking supply, that is, parking occupancy cannot be higher than 100%. If parking is fully saturated, cars have to search or wait for a free spot, leading to an increase of indirect costs. In the case of positive indirect costs before or after a price change, parking demand will react differently to a price change than in the case with no indirect costs. For instance, if parking is fully saturated and parking fees increase, **latent demand** may consume freed up parking spaces (Milosavljevic and Simićević, 2014; Nourinejad and Roorda, 2017). Latent demand classifies those drivers who did not, or could not, park due to the indirect costs caused by saturated parking.

Price Structures

Drivers may pay parking fees per permit, event or based on dwell time. A permit is the right to park at a specific facility. In the case of pay per event, drivers pay a flat parking fee when they enter or exit a facility. Dwell time dependent fees increase with the parking duration. Those fees shorten the parkers dwell time, implying more short-term parking. Those fees hence have a similar effect as short-term parking zones. It is sometimes argued that parking fees should not be dwell time dependent. As, dwell time dependent parking fees can even induce traffic, in the case of high demand. This occurs as a reduction in dwell time allows more cars to park within the same period, and because a lower occupancy increases the attractiveness of parking. This is why parking policies should always be designed in line with road pricing, as long as traffic regulation is an objective. In the absence of road pricing, parking fees with an event and a dwell time component can be used.

The price structure has a strong impact on the price elasticity. The more dwell time dependent parking fees are, the stronger drivers can react to price increases by shortening their dwell time. It is easier to save fees by shortening ones stay, if you pay parking fees per minute instead of per hour. The more a parking fee varies per time of day, the easier it is for a driver to respond to increases in charges by changing her parking times. The same is true for spatially differentiated parking fees.

Pricing Versus Supply Management

Parking space management regulates the demand of car parks in the short-run. In fact, parking space management plays a central role in urban traffic management. City administrators not only use it to control parking availability, but also traffic. Governments often see parking management as an alternative to road tolls (Glazer and Niskanen, 1992; Verhoef et al., 1995). Modern parking space management uses two instruments to regulate demand: prices and supply. The first means setting the level and structure of parking fees. The second includes restrictions on access to parking spaces at certain times of the day or during weekdays, limitations of parking dwell time, and restrictions on certain groups of drivers.

Pricing works fundamentally different to supply management. To understand the difference, we need to understand the cost components of using a car park, which are:

$$C = C_p + C_Q + C_O$$

Where C is the total cost of the car park, C_p are the driver's total parking fees, C_Q are all cost linked to getting a vacant parking spot (e.g., waiting time, discomfort of not finding a spot, costs of uncertainty, fuel consumed while cruising), and C_O are all other cost (e.g., access time to the parking spot, discomfort of parking in the sun). A car park is more attractive the lower C is, that is, when drivers can easily find a vacant spot for a low price.

Pricing directly affects C_p , whereas supply management directly affects C_Q . Higher parking prices increase the generalized cost of the car park, which leads to fewer people parking there (Lehner and Peer, 2019). Lower supply of parking space effectively increases the occupancy of the car park, which leads to fewer people finding a parking space, increases latent demand and the costs of getting a vacant parking spot, and hence the generalized cost of the car park. Indirectly pricing can also affect C_Q . This is as lower or higher occupancy affects the cost of getting a vacant parking spot. Supply management has two central flaws pricing can overcome. First, prices are more transparent to drivers, whereas drivers usually cannot tell how long they have to wait for a vacant parking space before they entered the car park. Second, pricing allocates parking according to the willingness to pay. Hence, in contrast to supply management, parking is allocated to best serve each individual, while minimizing waste and inefficiency. The second argument is also true for limitations of parking dwell time and restrictions on certain groups.

If parking is saturated, parking volume may increase or decrease with rising parking prices (Nourinejad and Roorda, 2017). Decreasing indirect costs, such as lower queuing and searching times, may cause an increase in volume. In extreme cases, occupancy may even stay unchanged. Drivers who are willing to shorten their dwell time are more likely to continue parking after a rise in the hourly parking fee. If parkers are not willing to shorten their dwell time, parking alternatives affect drivers' reaction to price changes.

Parking, Mode, and Activity Alternatives

Drivers may react to parking price changes by changing the parking location or the activity (Feeney, 1989). Changes of the driver's parking location may imply a change of the transportation mode. The elasticity of parking demand is greatly affected by the

availability and quality of alternative parking facilities, access time to those facilities, and transportation modes from those facilities to the final destination. Substitutes affecting the underlying activity associated with the parking event, include changing the parking dwell time (and hence the activities' duration), changing the parking (pull-in) time (and hence the timing of the activity), changing the location of the activity, or abandoning the activity altogether. Even though empirical data show that parking elasticity is mainly affected by parking and mode alternatives, substitutes affecting the underlying activity cannot be ignored. For instance, it is a common argument that parking prices in city centers should not be increased, as this would steer shoppers towards the suburbs. Additionally, parking fees can also be used to shift peak traffic, similar to temporal road tolls, as recent research shows (Fosgerau and De Palma, 2013; Lehner et al., 2019).

On- and Off-Street

When do drivers decide to cruise for an on-street lot and when do they decide to pay for an off-street lot? Which factors influence that decision? Shoup (2006) investigated those questions.

In his paper, he assumed that two parking options, one off-street (with high prices and infinite supply) and one on-street (with low prices and limited supply), compete for parking demand. A driver will prefer on-street parking if:

$$C^*(f + nv) < t(m - p)$$

where C^* is the expected time spent cruising for parking, f are the fuel costs per time unit of cruising for parking, n are the number of people in the car, v is the value of time spent cruising, t is the parking duration, m is the off-street price and p is the on-street price.

The expected time spent cruising for a free lot is a function of occupancy, the number of cars pulling-out while cruising and the amount of other vehicles cruising. The exact form of the function depends on the specifics of the car park. The time needed strongly increases with occupancy. The cruising time increases more, when occupancy increases from 90% to 100% than when it increases from 60% to 70%. As a rule of thumb, on-street parking occupancy should be lower than 85% per street block, to guarantee a vacant parking spot for drivers and to avoid cruising (Shoup, 2006).

Assuming that fuel costs, value of time saving, the number of people in the car, parking supply and demand for accessing the location by car are inelastic and constant, the demand for the two parking options solely depends on the prices of the on-street and off-street parking options. When on-street parking is cheap and off-street parking is expensive, drivers will be willing to cruise longer, leading to an increase in on-street occupancy. Drivers with a relatively low value for time savings, low fuel costs, a long parking duration and who are alone in their car, prefer on-street parking, while the others prefer off-street parking. It should be noted, that when the price gap between on-street and off-street parking is large, the demand for on-street parking may be completely inelastic, until its price gets close or exceeds that of off-street parking. At this point, it can suddenly become very elastic.

Commuters

Commuters owning a car and traveling from home to work primarily face two decisions: where to park and when to depart (Lehner et al., 2019). On the one hand, commuters can park at work. This implies that the way from home to work is driven by car. On the other hand, commuters may park at home. This implies that they travel the total distance with an alternative mode of transportation. In all other cases, they park in facilities between their home and work, such as Park & Ride facilities. They also have to decide when to depart. Commuters try to avoid congestion and arriving either too early or late at their workplace, or leaving too early or late from home. Similarly, when they commute home, they try to avoid congestion and to appropriately time their departure from work or arrival at their next activity (Arnott et al., 1990; Zhang et al., 2008). When commuter parking is in high demand and fills-up in the morning, commuters may try to leave earlier from home to find a vacant spot and reduce their search time (Arnott et al., 1991). Parking fees reduce demand and hence ensure sufficient vacant parking spots. Thus, parking fees also impact the departure time of commuters.

Time-varying parking fees, that is, parking fees that vary by the time of day or are only charged within a certain period of the day, additionally affect the departure decision of commuters. This occurs as commuters may change their parking times in a way that avoids or reduces parking costs (Fosgerau and De Palma, 2013). Similarly, spatially differentiated parking fees, that is, parking fees that are higher at certain locations, can incentivize commuters to park outside of a specific zone. For instance, high parking prices within the city center provide incentives for commuters to park in Park & Ride facilities, outside of the city center (Qian et al., 2012).

If commuters do not have to drive to work, higher parking prices at the workplace can also lead to an increase in the number of employees working remotely. This assumes that working at home reduces commuters' parking fees. Commuters can save on parking cost, when they are paid per commute and not per month or year. Then the price structure allows for short-term savings. As a bottom line, traffic managers can use parking fees as an instrument to tackle congestion.

Subgroups

Sometimes articles report elasticities for subgroups of drivers. As with all elasticities, these subgroups have to be interpreted with care. Elasticities for each subgroup (such as commuters, shoppers and business activities) strongly correlate with the elasticities of each of the other subgroups, in particular when parking is saturated. For instance, consider a nearly fully saturated parking garage that

increases their hourly parking price from 1.00 EUR/hr to 2.00 EUR/hr. Before the price increase, commuters mainly used the garage. Due to the higher price, the parking volume of commuters decreases by 50%. The price elasticity for the subgroup commuters is -1 . As parking availability during business hours has now strongly increased, 100% more shoppers use the garage. Some might argue that the price elasticity of shoppers is positive. The increase in shoppers, however, is not due to the higher price, but due to the increase in parking availability. Similarly, it is possible that the higher parking availability attracts new commuters. To calculate reliable elasticities, the effect of parking availability on demand has to be disentangled from the effect of the parking price on demand.

Data Collection and Calculation of Elasticities

Data

Data on parking demand can be collected by observing the parking space or the driver. A sensor installed at the entrance of a car park or at each parking lot, can detect how many spots are occupied. Sales data are a good proxy of how many parking hours drivers consume. However, often the amount of paid parking hours strongly diverges from the amount of consumed parking hours, as drivers under or overpay for parking. If no sensors are installed, the number of occupied lots can also be counted, whether manually or with technical equipment. Questionnaires can reveal not only how drivers behaved, but also how they intend to behave. However, the stated behavior of a responded can deviate greatly from the actual behavior. Data from devices connected to the internet, can measure where and how long drivers park. Since the number of connected devices is increasing rapidly at the time of writing, this data source might well be of greater relevance in the coming years. Each data source has their advantages and disadvantages. Generally, sensors give detailed information about parking volume, dwell time and occupancy within a parking facility. Data based on counts, reveal the occupancy level of the investigated parking facility, however, they often provide less accurate or no information on volume and dwell time. In contrast to parking space based data, questionnaires give insights into why and which drivers park at a certain location. Data based on connected devices, can also provide this information. Similarly, to questionnaires, data based on connected devices might also reveal the alternative behavior chosen, when drivers decide to stop parking altogether. When predictions are made on data based on drivers, the underlying distribution of the population should be known. This knowledge allows for correcting of sample biases.

Calculation

There are many possibilities on how to calculate price elasticities. The applied method depends on the underlying data. Revealed preference data is data stemming from an actual change in parking prices. For instance, in Vienna the hourly parking fees in the most central district increased from 1.20 to 2.00 EUR/hr. Urban planners may be interested in how the increase affected parking occupancy at noon. Hence, the occupancy levels for multiple days before and after the price increase are collected. The occupancy level of on-street parking at noon is then calculated by dividing all parked cars by the total parking supply. The occupancy will probably fluctuate between days. The fluctuation decreases with the number of parking lots under consideration. In addition, parking occupancy usually fluctuates strongly between weekdays, months and time of day. Furthermore, other external factors may affect the parking occupancy in the district. Assuming that the occupancy is not fluctuating between days and no external factors affect the occupancy, the elasticity can be calculated with the arc-log elasticity equation:

$$\varepsilon = \frac{\log \frac{Q_1}{Q_0}}{\log \frac{P_1}{P_0}}$$

where ε is the elasticity, Q_0 the old demand (e.g., occupancy, parking volume), Q_1 the new demand, P_0 the old price, and P_1 the new price. The log transformation accounts for the non-linearity of the demand curve. Furthermore, the elasticity is calculated for the average percentage change in quantity and price. Hence, the elasticity is the same for the concerned observation regardless of whether the price increases or decreases. This is because the formula uses the same base for both cases. In the point elasticity the old or the new price is used as the base. A price elasticity of parking demand of -0.5 , thus indicates that a price increase of 67% leads to a drop of occupancy of 23%.

Most papers in transportation economics use econometric models. In econometric models with a continuous dependent variable, the price elasticity is the estimated regression coefficient β of the price variable. In econometric models with discrete dependent variables (i.e., binary choice models), the elasticity can be calculated with the individual or aggregate elasticity formula. The individual formula is:

$$\varepsilon = \beta \times (1 - q) \times p$$

where, q is the share of the demand (regression estimate) at the sample means and p is the sample mean of the parking price. It should be noted, that binary choice models explain the behavior of individuals, while policy makers are usually concerned with the behavior of the population of interest. The individual formula calculates the elasticity that predicts how an individual, with the characteristics of the sample mean, reacts to a price change. However, if the behavior of the broader population is of interest, the

aggregated elasticity should be used (Westin, 1974). The aggregated (or weighted) elasticity, first computes the specific distribution of characteristics over all individuals, before the aggregation takes place. Aggregate predictions take into account the frequency of each individual in the population. In most applications, the price elasticity calculated with the individual formula will be higher (in absolute terms) than the price elasticity calculated with the aggregate formula. This occurs as the majority of the driver's decisions lie on the concave part of the logic function in choice models. It should be noted, that the difference between an elasticity calculated with the individual formula and the aggregated formula, could be substantial.

Empirical Values

The majority of empirically measured parking elasticities fall in the range of zero and minus one. They are negative and inelastic. This generally implies that a rise in parking prices leads to a lower parking demand and an increase in parking revenue.

Lehner and Peer (2019) state ranges of price elasticities for commuting and non-commuting trips, based on 50 parking studies. For non-commuting trips the baseline price elasticity of occupancy is -0.63 , which is the sum of the price elasticity of dwell time of -0.30 and the price elasticity of volume of -0.32 . For commuting trips, the baseline price elasticity of occupancy of -0.32 equals the price elasticity of volume. Commuters probably do not shorten their dwell time to reduce parking costs.

The empirical results show that commuters react differently to increasing parking prices than non-commuters. In the absence of parking alternatives, non-commuters mainly shorten their parking dwell times and do not switch to other transportation modes, whereas commuters stop to park at the concerned facility (Lehner and Peer, 2019). Multiple factors might explain this difference. First, commuters cannot shorten their parking as easily as non-commuters, as the underlying activity – working – is more rigid. Second, when drivers can and are willing to shorten their parking dwell time, they are less likely to give up parking altogether. Third, as commuting is a recurrent activity, drivers are more knowledgeable about alternative transportation modes. Finally, the impact of parking fees is stronger for commuters, whereas it is only marginal for non-commuters. On average, commuters pay 13% of their daily gross income for parking, when parking is being charged. The parking price elasticity of commuters is around -0.5 based on revealed preference data and -1.1 based on stated-preference data.

Elasticities based on stated preference data (data collected in hypothetical choice experiments) are systematically lower than elasticities based on revealed preference data (data collected from real price changes). This might be due to two reasons. First, stated preference experiments suffer by hypothetical bias. Participants can indicate that they would change their behavior, but when confronted with the actual situation, they do not. Second, stated preference experiments do not account for supply restrictions or for indirect costs. Supply restriction, however, may affect parking elasticity to a substantial degree (Lehner and Peer, 2019).

The Pareto Criterion and the Kaldor–Hicks Criterion

Definitions

These criteria will apply to a society (usually taken to be a country) consisting of a given number of individuals. Different policies or options are open to the society. Given the policy chosen, a given amount of goods and services will be available at the aggregate level. Either by the action of the individuals themselves or government, or by the interaction of both, each individual will get a certain share of it. An *allocation* is a distribution of the total amount of goods and services to each of the individual members of society. Each policy results in an allocation.

A *reallocation* is a measure taken to change the allocation after a policy has been implemented.

This highly abstract view of society abstracts from time (time only exists in the form of before and after a policy is implemented), and it says nothing about the mechanisms that bring about a certain allocation, be it production, trade, or the individuals' own choices of how much to work, what to consume and how to spend their time in general. In particular, utility maximization and profit maximization have not been assumed.

The individuals are, however, thought to be able in all circumstances to tell if a bundle of goods and services is better, worse, or just as good as another. That is, they have a *complete and transitive preference ordering* over such bundles.

Definitions Concerning the Pareto Criterion

The Pareto criterion provides the following sufficient condition for an allocation to be better than another:

- An allocation is better than another (constitutes an improvement from the base case allocation) if at least one member of society is better off and nobody is worse off.

If this is the case, the allocation is called a *Pareto improvement* and is deemed worth carrying out. Note that if only one single person is worse off, the allocation is not a Pareto improvement, even if all others are overjoyed by it. In such situations — certainly the majority of cases — the Pareto criterion cannot decide whether or not a policy should be implemented.

When no Pareto improvements are possible, that is, nobody can be made better off without making someone else worse off, we have a *Pareto maximum*.

Definitions Concerning the Kaldor–Hicks Criterion

A *potential Pareto improvement* is a situation where those that are made better off by the policy measure, can in principle compensate those who are made worse off (so that they are at least as well off as before), and still be better off themselves. Put otherwise, in the situation after the policy has been implemented, there is at least one reallocation that can make at least one individual better off, while making no one worse off than before the policy was implemented.

The Kaldor–Hicks criterion simply says:

- A policy which brings about a potential Pareto improvement is worth carrying out.

We note that the concept of economic efficiency as defined and computed in transport cost benefit analysis, is essentially the same as to satisfy the Kaldor–Hicks criterion.

The Pareto Criterion

History

To the early utilitarianists, like Jeremy Bentham and John Stuart Mills, it seemed obvious that the best action was the action that produces the greatest well-being to the greatest number of people, and that somehow, the level of attainment of this goal was measurable.

The Italian economist and sociologist Vilfredo Pareto (1848–1923) thought otherwise. To him, the utility of one individual and that of another could never legitimately be added or compared. Every person is indeed able to compare, rank, and choose among different outcomes for herself, but interpersonal comparisons make no sense.

So how can we pass judgment on policies that affect more than one person? Pareto came up with a criterion that does not require more than that, each affected individual is able to rank any set of policies presented to her (her preferences induces a complete and transitive ordering on the set of policy options), and that she prefers more rather than less of any good. This is the Pareto criterion, and it may be shown that it is indeed the strongest possible criterion that does not involve interpersonal comparisons.

Utility may be measured on an ordinal or cardinal scale. Measurements are on an ordinal scale if they are used for ranking purposes only. Cardinal measures, on the other hand, are based on an underlying scale which makes it meaningful to do computations. Your utility is twice the size of mine, the difference between yours and mine is 23, etc.

Pareto's concept of utility was ordinal—utility differences exists, but the level of utility, the size of utility differences, and the concept of marginal utility have no intrinsic meaning. Consequently, interpersonal comparisons are also meaningless. Other important economists, such as [Hicks \(1939\)](#), [Samuelson \(1956\)](#), and [Sen \(2018\)](#) came to exactly the opposite conclusion: Even if a cardinal and measurable concept of utility is not needed to derive the demand functions of individuals, interpersonal comparisons not only make sense, but they are also necessary for policy purposes. If a cardinal utility concept is needed for such purposes, so be it.

Both approaches have lived on, but it is fair to say that the cardinal approach has lost much ground in academic circles, while the ordinal approach has become more and more formalized. Perhaps to the point where, as K. J. Lancaster once remarked, it now stands as an example of how to extract a minimum of results from a minimum of assumptions. In the applied fields of economics, however, and perhaps more than anywhere else in transport economics, the cardinal approach has spread and developed over the last half century in the form of cost benefit analysis.

Transport Applications of the Pareto Criterion

The Pareto principle is seldom applied in transport economics. The main reason is that major transport infrastructure projects are nearly always financed by taxes. Among the taxpayers, there will usually be many that will make no use of the new infrastructure, and so there is a large group of losers that cannot possibly be compensated without undermining the financial basis for the whole project. The possibility of applying the Pareto principle might be a little better if we consider a more comprehensive urban or national transport plan, consisting not only of road projects, but also projects concerning public transport, walking, and cycling. But even then, there will be many people who stand to lose.

Research on the political processes that produces such transport plans have shown that there is a tendency to distribute projects among districts in such a way that those left out of the current plan will be first in line for projects in the next plan. In the end, every taxpayer will get something back, it is thought (and sometimes even openly said or formally agreed). Such processes are often accused of wasting taxpayers' money by including a lot of economically inefficient projects. Could it possibly be, however, that in the best of cases, they do at least produce a Pareto improvement? If the best plan according to a cost-benefit analysis (the Kaldor–Hicks criterion) is infeasible because the losers understand that compensation could not possibly be paid (or at least will not actually be paid) there might still be some room for rational bargaining for a Pareto improvement.

If we turn from infrastructure plans to pricing and regulation, the potential for actual Pareto improvements increases considerably. More efficient ways of regulating traffic, providing information to users, and utilizing existing infrastructure and rolling stock may cost little and (in the best of cases) impose no extra inconveniences on anybody. Manuals with ideas for such "small projects" exist.

Congestion charging and other forms of marginal cost pricing split the users into three groups: The first group opts out, and will incur a loss, the size of which depends on the best remaining alternative. The second group also stands to lose but finds that paying the price and staying in is a lesser evil than the other remaining alternatives. Members of the third group are the only ones who find themselves better off in the new situation, for instance because they have a very high willingness to pay for time savings on the road, for getting a seat in the bus, etc.

A fourth group — the second winning group — is the public sector, who gets the revenue from the charges. It is almost a matter of definition of marginal cost pricing that this last group could reimburse the three others and still have something left. (It will probably not be able to save some money by identifying the members of the third group.) But doing so would be meaningless: If all travelers understand that they will get their money back regardless, they will not change their travel habits. The potential Pareto improvement in this case actually could not be made a reality, at least not in the straightforward way by reimbursing the tolls. The compensation

must either be made in kind, for instance by improving public transport, or paid out with an equal amount to all inhabitants in the district. Either way, there will still be losers, but not so many, and not by so much.

We see that the Pareto principle has a role to play in transport as a complement to the Kaldor–Hicks criterion. There is a moral reason for this: We feel obliged to reduce the number of losers from a policy and the severity of their loss. Potentiality becomes a hollow phrase if it cannot ever be transformed to reality. And there is a practical side: All our congestion charging plans tend to be turned down if we do not pay attention to compensating the losers.

The Kaldor–Hicks Criterion

Theoretical Problems

To apply the Kaldor–Hicks criterion, we must be able to express the losses of some and the gains of others on a common scale, preferably money. According to microeconomic consumer theory dating back to [John Hicks \(1939\)](#), this can be done in two different ways: the equivalent variation (EV), and the compensating variation (CV). The first is the answer to the question of how much money one would be willing to pay to get the benefits of a proposed policy, and the second answers the question of how much one must have to forego these benefits.

There is also a third way, commonly associated with Alfred Marshall, but actually dating back to the French engineer [Jacques Dupuit \(1844\)](#). This is the consumer surplus (CS), consisting of the area under the ordinary demand curve for the good that the policy provides. This measure lies in between the two Hicksian measures, both of which coincide with the CS under special circumstances.

It turns out that there are theoretical problems with each of these. For instance, it could be shown that using EV or CV, it might sometimes happen that starting from the “do nothing” situation, doing “something” is judged to be an improvement, while starting from the situation where this “something” has already been implemented, going back to the original situation is also judged to be an improvement (Scitovsky reversals). The CS, on the other hand, lacks the straightforward interpretation and general applicability that EV and CV have.

In the fifties, it was shown by W. F. [Gorman \(1953\)](#) that for consistent interpersonal comparisons to be made, and consequently for computing the aggregate losses of the losers and the aggregate gains of the winners and comparing them with one another, the utility functions of all individuals must be of a particular mathematical form, the so-called Gorman Polar Form.

Let $\mathbf{p}$ be the vector of prices of the goods and services that concern us here, and let R_h be the income of individual h . The indirect utility function $V_h(\mathbf{p}, R_h)$ of individual h is of the Gorman Polar Form if and only if it takes the form

$$V_h(\mathbf{p}, R_h) = a_h(\mathbf{p}) + b(\mathbf{p})R_h$$

The function $a_h(\mathbf{p})$ is specific for individual h , while the function $b(\mathbf{p})$ is the same for all individuals. Summing over individuals, we get the (utilitarian) welfare function:

$$V(\mathbf{p}, R) = \sum_h a_h(\mathbf{p}) + b(\mathbf{p})R$$

where R is the sum of all individual incomes. It is seen that this welfare function has the same form as the individual indirect utilities. That the utility functions of all are of the Gorman Polar Form is not only the condition for consistent interpersonal comparisons to be made, it is also the condition for there to be a representative consumer, that is, for the aggregate decisions of all consumers to correspond to consumer theory applied at the aggregate level.

It is evident from the formula that welfare, as measured in this way, stays the same regardless of changes in the income distribution. Another property of this function is that even if the individuals differ in their income and tastes, they are all equal in the sense that if they get a marginal increase in income, they will all spend it in the same way. (The derivative of the demand functions with respect to income are the same for all individuals.)

It has been shown by [Chipman and Moore \(1979, 1994\)](#) that to apply the Kaldor–Hicks criterion in a situation where reversals cannot exist and to apply the consumer surplus (CS) in the situation where a representative consumer exists is basically one and the same thing. Chipman and Moore called the Kaldor–Hicks criterion restricted to situations without reversals of any kind for the Kaldor–Hicks–Samuelson criterion (KHS-criterion for short).

Where does that leave us?

It might seem that the conditions for applying the Kaldor–Hicks criterion in a consistent way are so special that they almost never will be fulfilled. But given the models that we have, this is not necessarily true. Take general equilibrium models as an example — they almost always apply representative consumers, and even if there are more than one of them, they may be sufficiently similar to be compared.

Partial equilibrium analyses are often even more close to the conditions for the Kaldor–Hicks criterion to apply. Because we only model a small part of total consumption, we abstract from the prices of most goods and services, and often from the income effect in the markets of interest. That is, demand in these markets is not supposed to be a function of income. This is really to apply the Gorman Polar Form.

It may be objected that even if the necessary conditions apply to the model, they certainly do not apply to reality. But if we find the models useful and enlightening, there is no intrinsic reason why their consumer surpluses cannot be useful and enlightening too. They will never be entirely accurate, but they may at least be good indications of the true consumer preferences.

Quasi-linear Utility: Problem Solved, But Reappearing

Setting $b(\mathbf{p}) = 1$ in the equations above, we get the quasi-linear indirect utility function. The direct utility function in this case is $U = z + u(\mathbf{x})$, where z is some composite good and $\mathbf{x}$ is a vector of the goods and services we want to model in more detail. This model is of the Gorman Polar Form, a representative consumer exists, the indirect utilities of all individuals can be added, and the Kaldor–Hicks criterion can legitimately be applied. Furthermore, the model divides the economy nicely in a sector of interest where a diverse set of goods $\mathbf{x}$ belong (the transport sector, for instance), and a single composite good z representing everything else.

But this is only as long as we maximize U subject to one single constraint – the budget constraint. But often, we want to apply constraints on total available time as well (the time budget), and maybe on the various forms of time use. The minimum number on working hours, for instance. The [de Serpa \(1971\)](#) model of the allocation and valuation of time, that has formed the basis for most studies on the valuation of travel time savings in transport, is a case in point. The two constraints are reduced to one if we define total income not as R , as usual, but as $R + wt_w$, where w is the hourly wage and t_w is the number of working hours. Since t_w also figures in the time constraint, we may solve that second constraint for t_w and insert the result in the budget constraint. Maximum potential income is then $R + wT$, where T is total available time, while the trips all have generalized costs, that is, costs composed of a monetary cost and a time cost (trip time times the wage rate, possibly modified by the shadow prices of additional constraints on time uses).

The existence of the additional form of income wt_w disrupts the separation of the indirect utility function in one part that is a function of income and another part that is not. So the Gorman Polar Form no longer applies here, and conditions for the Kaldor–Hicks criterion to be used are not fulfilled.

The Kaldor–Hicks Criterion and Standard Transport Appraisal

The key issue in the appraisal of transport plans and projects is often if the time savings cover the monetary costs. To judge about that, we need to know the value of an hour of travel time savings in different modes and under different circumstances. National and international guidance on this issue is based on average values from stated preference value-of-time studies. Already here it becomes apparent that there can be no question of identifying winners and losers among the travelers based on their individual values of time. They will all be versions of the average traveler in the different settings that he experiences – short and long trips, work and leisure trips, car and public transport trips.

It might, of course, be quite clear that a given policy benefits individuals using public transport, for instance, while car users stand to lose. But this is on the average and might be different in individual cases. And indeed, the same person might win as a public transport user and lose as a car user. Apart from that, the Kaldor–Hicks criterion boils down here to the question if the “multiplied average traveler” can compensate the public sector, the transport operators, and the environment for the costs they incur.

It seems that to substitute the average traveler for the representative traveler does require some sort of justification. We are certainly not compelled for theoretic reasons to follow the average traveler everywhere he goes, but his views might nevertheless be of considerable interest. And in fact, as the distribution of individual values of time in stated preference studies is always skewed to the right (most people have lower values than the average), assuming that those who benefit from a project are also those that have to pay, more projects get selected using the average value of time than by voting (the mean is to the right of the median).

But by the very nature of things, a cost-benefit analysis using values of time from national guidebooks (that is, average values), should always be accompanied by at least some thoughts about distributional consequences – and possibly by some forms of compensation to the losers.

The Kaldor–Hicks Criterion and Random Utility Models

If the model is of the GEV family and the marginal utility of money is constant, the logsum formula is a valid welfare measure. It is basically identical to the consumer surplus (CS) welfare measure in the deterministic case. The conditions for it to apply are the same, and when the conditions are met, the EV and CV coincide with the CS, just as in the deterministic case.

The problem is, however, if the marginal utility of money is indeed constant in the case at hand, and what to do if this is not the case.

It may be shown that when the marginal utility of money is not constant, no representative individual exists, and the Kaldor–Hicks criterion does not apply. However, [Anders Karlström \(1999\)](#) has derived an exact and computable measure of expected user benefits (expected equivalent and conditional variations) that may be used for cost-benefit analysis with GEV models in which marginal utility of money is not assumed to be constant. So, if instead of deterministic values we are willing to make do with expectations; and if the concept of the average (mean) individual is accepted, then a meaningful welfare measure exists even in such models.

Alternative Approaches

Aggregate Willingness-to-Pay

Seeing that individual consumer surpluses, equivalent variations or compensating variations cannot legitimately be added without explicit or implicit assumptions on the weight of each individual in the welfare function, some economists have pointed to the following solution: If the aggregate willingness-to-pay in the concrete situation at hand is higher than the costs, the project or the plan should be carried out.

This criterion is impractical, because it requires a local valuation study to be carried out for each alternative in each project proposal. That would be expensive. And unless the stated amounts of money could actually be collected afterwards, the respondents would have every incentive to exaggerate their willingness to pay. A compromise solution could be to regularly carry out valuation

studies of a more general type at the local level. But even that would be very expensive, and the chances would be high that the incentive problems would persist.

Voting Theory

Transport project appraisal consists of a cost benefit analysis summing up the monetarized impacts plus an analysis of non-monetary impacts. If we let every impact (or suitable aggregate of impacts) be a “voter”, as it were, and let each of these voters rank the alternatives, there will be many different ways of using this information to pick a winning alternative or form an aggregate ranking. Voting theory is both a very old field of research and a very alive one (https://en.wikipedia.org/wiki/Category:Voting_theory). If one does not want to apply the Kaldor–Hicks criterion and do a cost benefit analysis, some form of voting theory might be considered, or at least it can be applied to the nonmonetary impacts. We cannot get around Arrows impossibility theorem,^a but we may for instance be able to define sets from which the winner must be chosen.

Another possible approach is to find a ranking of the alternatives that minimizes the distance to all the individual rankings, as measured, for instance by the minimum number of permutations needed to transform all individual rankings to an aggregate one.

Both voting theory and rank aggregation by permutations can be seen as forms of multicriteria analysis, but with set rules instead of subjective expert opinion.

Conclusion

The strict conditions for the aggregation over individual consumer surpluses to form a consistent measure of how much a policy is worth to society are not often met in real life. This means that the Kaldor–Hicks criterion cannot be applied without simplifying assumptions, either on the form of the demand functions or on the legitimacy of interpersonal comparisons. But even if it can, compensations to loser are often not feasible, not even in theory. This implies that there is a role for the Pareto criterion to be applied in conjunction with the Kaldor–Hicks criterion, to avoid policies with adverse distributional impacts or design compensating schemes to accompany them. There might also be a role for methods based on theories with less strict assumptions than the consumer theory of economics.

Introduction

Although the value of travel time may be the shiniest star on the canopy of economic parameters in evaluations of transportation infrastructure, it often is the rate of discount that determines their bottom-line destiny. The force of exponential discounting effectively dwarfs long-term returns from such investments, to the disadvantage of objects with a long construction period and long life, such as new railroads, highways, airports, or ports. At a 6% rate, 56 dollars present value remain of a 100 dollars benefit that arises in 10 years from the present and only 5 dollars if it arises after 50 years. On the other hand, at a 1% rate such a benefit represents a present value of 91 and 60 dollars, respectively. Unfortunately for the credibility of the outcome of the economic evaluation, in spite of these huge differences in effect, both rates can be arguably plausible, based on theoretical and empirical reasoning. The precise motives for discounting and arguments for choosing a specific level or range of discount rates therefore deserve much attention.

General

Concepts

The discount rate is used to convert monetary valued benefits and cost, or the cash flow, at different points on a time line to a common metric, which is the value at a specific time, for instance the current, called the present value, or the future value at some specific later time, for instance when operation of services starts. The process of moving values from the future to the present is called discounting, while going in the opposite direction is called compounding. The conversion over the time line is made by multiplication with a discount factor $D(t_0, t)$ that often is defined as:

$$D(t_0, t) = (1 + r)^{(t_0 - t)} \quad (1)$$

in discrete time (for instance, years), where t_0 is the time used as reference and t is the time when the benefit or cost accrues. r in this formula is the rate of discount. The corresponding formula when time is given as a continuous variable is:

$$D(t_0, t) = e^{r(t_0 - t)}. \quad (2)$$

This second expression tells that the discount factor declines (and the compounding factor increases) exponentially over time at a speed that is determined by the discount rate. However, these mathematical expressions are not generally valid. Many argue that the

discount rate should, for various reasons, decline over the very long term. Expressions in Eqs. (1) and (2) are convenient and lead to time consistency (see explanation later), but may be unrealistic, at least for a long time horizon.

Motives

There are two main motives for discounting, both related to how economic value is affected by distance in time, giving rise to costs of time distance. The first is the cost of waiting and the second is the cost of uncertainty. The rate of discount is affected by both and can be split in two parts: the risk-free rate that reflects the cost of waiting and the risk (or uncertainty) premium, which captures the cost of risk (or uncertainty).

The Cost of Waiting

The cost of waiting derives from postponement of consumption or investment, or both. Let's start with consumption. Consumption gives utility to the individual and individual utility gives welfare to society (abstracting from negative externalities). Both individual utility and social welfare of a given basket of consumption goods are likely to decline with the distance in time. First, individuals may for several reasons have a genuine preference for being able to consume now rather than later. Very fundamentally, individuals are mortal, which means that the expected utility of consuming later is less than consuming now, since there is a positive probability of zero utility because of death. At the societal level, individual death is less of an issue, but still there is nonzero probability of extinction (from pandemics, nuclear war, comet hitting earth, etc.). Also, decision power belongs to the current generation that may have a preference for its own utility over that of future generations, especially of those that are much distant in time. Second, marginal utility of consumption (i.e., the additional utility from a small increment of consumption) declines with income. Therefore, if there is economic growth (increase of GDP per capita) then the individual will be richer in the future and future generations will be richer than the present. Hence, the marginal utility of future consumption will be lower, and this needs to be compensated. To put it bluntly, why should otherwise a poor current generation make sacrifices for future rich generations?

Then there is investment. Instead of consuming 1 unit today you can save and invest it so that you can consume $1 + r$ units tomorrow. Hence, there is an opportunity cost of using resources that could be used for productive investment that yields an expected positive return. To invest more in for instance infrastructure, it may be necessary to forsake investment in housing, machinery equipment, education, research, etc., that would have generated resources for future consumption.

The Cost of Uncertainty (Risk)

Future outcomes are uncertain. When possible outcomes and their probabilities are known it is called risk. The risk can be measured by one single parameter, the standard deviation, or the volatility, when future returns from investment follow a known normal probability distribution. It should be noticed though that extreme events, such as an outcome four standard deviations away from the mean, are utterly unlikely in a normal probability distribution, but in real life disasters do happen and that should affect decision-making.

Anyway, what is important to individual utility and societal welfare is not the volatility of a specific asset, but that of overall consumption possibilities as represented by wealth, which is a portfolio of assets including housing and human capital, and, on the societal level, overall consumption per capita (and its distribution). Therefore, the cost of investment in a risky asset is related to how the volatility of returns from that asset contributes to the overall volatility of wealth, or consumption per capita. The crucial aspect is therefore not total volatility of an asset but only the part that covaries with wealth or consumption.

The two aspects of the cost of time, waiting and risk, means that the rate of discount will consist of, at least, two components, the "risk-free" rate that reflects waiting and a "risk premium" that is the product of a general risk premium and a factor (beta) that reflects systematic risk.

Discount Rates in Private Investment

A basic framework in financial analysis of private capital is the Capital Asset Pricing Model, or the CAPM, developed in the 1960s by William Sharpe, John Lintner, and Jan Mossin. This model states that in equilibrium investors get a return r_i on a risky asset equal to the return r^f on a risk-free asset plus a risk premium equal to the premium $r^m - r^f$ on a fully diversified market portfolio of risky assets, called the equity premium, times β_i . These two terms thus represent both the cost of waiting and uncertainty. The "beta" is a measure of the nondiversifiable systematic risk, equal to the covariance divided by the variance, or the slope coefficient in a linear regression of the return on the specific asset with market portfolio return. Thus,

$$r_i = r^f + \beta_i (r^m - r^f) \quad (3)$$

where $\beta_i = \frac{\text{Cov}(r_i, r^m)}{\sigma_m^2}$.

A private capital investment is often funded from several sources that come with varying return on investment requirements. One reason for such differences is that the burden of the investment risk is unequally shared across sources, for instance by a lower risk on holders of bonds than on owners of stocks, the latter only having a residual claim. A second reason is that because of anticipation of future macroeconomic events, yield requirements on bonds and other securities at different terms, or maturities (i.e.,

time to repayment of principal) can vary. This is called the term structure. A third cause is different tax treatment, for instance because a firm's payment of interest rates, unlike payment of dividends, is deductible. As firms for various reasons want to spread funding over multiple sources, hence with varying rate-of-return requirements, investment projects are often evaluated by a Weighted Average Cost of Capital (WACC) rate, with each source's share of the funding as weights.

Social Discount Rates

A social planner that wants to get an appropriate discount rate for evaluation of a public funded program, that is, the social discount rate (SDR), has a basic choice between using a market-based rate or an estimate of the social rate of time preference. The main argument for the first approach is that it will reflect the actual opportunity cost of the resources used in the public program, and the main argument for the second approach is that social preferences may not coincide with market-revealed preferences.

The Market-Based Approach

The *market-based approach* uses the same rate of return requirements as for private capital. The main difficulty in implementation is the multitude of such rates to choose among. Rates come nominal or real valued, before tax or after tax, with a term structure, and vary depending on the risk of the underlying security in ways that still are not very well understood. An important aspect when navigating in this zoo is whether an investment is evaluated in a closed or in a (small) open economy. Early literature focused on the former case and suggested an approach for estimation of the SDR based on a weighted average of after-tax returns received by consumers and pretax return paid by private capital. This approach is still used for the federal guidelines for government CBA in the United States. However, in small open economies that are part of the global financial market, this approach, based on the idea that increased public spending crowds out domestic private consumption or investment, is less relevant as the opportunity cost of public spending is predominantly the (pretax) global market rate. In several countries, recommended SDRs are based on the cost of government borrowing, for instance as in New Zealand on the 5-year real risk-free government bond rate. Obviously, that rate does not consider project-specific risk. This is in contrast to the United States, where the recommended rate exceeds the rate on US government bonds, so that it, to a larger extent, corresponds to the long-term average return on a well-diversified portfolio of equities.

The Social Time Preference Approach

The social time preference (*STP approach*) has been developed along two lines in the theoretical literature: (1) the Ramsey model, which is originally based on deterministic conditions, and (2) the Consumption Capital Asset Pricing Model (CCAPM), which explicitly considers project risk. The first has its origins in a study by Frank P. Ramsey in 1928 who asked how much a nation should save. To answer this, he set up a model where social welfare is expressed as the sum of an infinite stream of instantaneous utility $u(C_t)$ from consumption C_t discounted at a constant rate δ . Maximizing social welfare specified in this way results in a first-order condition that, with some simplifying technical assumptions (iso-elastic utility and a constant rate of growth of consumption per capita), gives the *Ramsey equation*:

$$r = \delta + \gamma g, \quad (4)$$

where δ is the pure rate of time preference, γ is the elasticity of marginal utility with respect to consumption, and g is the rate of growth of consumption per capita. The first term is due to unequal weighting of utility of different generations or impatience within a generation, or both. The second term takes care of the fact that a long-term investment in a growing economy is a transfer from the poor (current generation) to the rich (subsequent generations), and adjusts the discount rate in proportion to the expected relative decrease of the marginal utility of consumption due to growth in consumption per capita. The Ramsey equation can also be derived in an overlapping generations model, which avoids the unrealistic assumption of an infinite time horizon, and leads into explicit consideration on whether δ reflects within life-cycle time preference or the current generations preferences for the utility of future generations, or both.

Several authors have derived an augmented Ramsey rule for stochastic consumption growth, thus introducing macroeconomic risk. Assuming that consumption per capita follows a geometric Brownian motion process with trend μ and independent and identically normally distributed stochastic terms with standard deviation (volatility) σ , an augmented version of this rule can be derived:

$$r = \delta + \gamma g - 0.5\gamma(\gamma + 1)\sigma^2. \quad (5)$$

The new term on the right-hand side is the precautionary effect on SDR. It reduces the SDR and thus to some extent promotes investment (in safe assets) as a means for hedging against volatile consumption (i.e., saving for a rainy day). However, the standard deviation of consumption growth in many advanced countries is small so the reduction of SDR is of second-order importance within the transportation-planning horizon. However, if growth rates shocks are persistent, because of serial correlation in error terms or regime switches (for instance, representing the possibility of catastrophic depressions), the precautionary term will not be constant

but grow over time from today's perspective. This gives rise to a substantially declining SDR, which means that the precautionary effect will be large when discounting benefits in the far future, as for instance in the case of climate policies. As shown in several works by Martin Weitzman, a similar effect arises when future SDRs are uncertain for whatever reason. The basic explanation is that the expected present value is a probability-weighted average of discount factors (see Eqs. (1) and (2)) and that these decline faster for high discount rates than for low rates. These arguments have led several countries to recommend declining SDRs (sometimes called hyperbolic discounting). A possible drawback is time inconsistency, which means that a decision-maker can come to different conclusions on the same investment prospect depending on when the decision is made. For instance, the optimal time for rehabilitation of a road may be different if it is assessed when the road is built or at a later point of time.

The Consumption Capital Asset Pricing Model

The Model

The second model, the CCAPM, is derived in a framework where a representative consumer maximizes the total expected utility from current consumption $u(c_0)$ and expected future consumption $Eu(c_1)$ discounted with the utility discount rate δ . This model adds to the augmented Ramsey equation by consideration of investment risk. Again applying some simplifying technical assumptions (iso-elastic utility, growth is a Brownian motion with trend and returns and the log of per capita consumption are jointly normally distributed) to the first-order condition gives the CCAPM equation:

$$r_i = \delta + \gamma g - 0.5\gamma(\gamma + 1)\sigma^2 + \beta_i\gamma\sigma^2 = r^f + \beta_i\pi. \quad (6)$$

Hence, this amends the augmented Ramsey equation (Eq. (5)) with a fourth term, but, as shown, the right-hand side can be nicely summarized into a sum of two terms: the risk-free rate and the risk term. The risk term is the product of the project-specific beta, β_i , and the average risk premium, π . The project beta is a measure of how the total consumption per capita risk (volatility) is affected by the project. It is defined as the covariance between the project returns and overall consumption per capita over the variance of consumption per capita. The average risk premium is the product of the marginal utility of consumption and the variance of consumption per capita. The similarity to the CAPM is no coincidence; CCAPMs (and other consumption-based approaches) are closely related to the CAPM. It can be noticed that total consumption can be regarded as the returns from all individual projects (including investment in human and natural resource capital), which implies that average beta is unity. As a large part of total consumption in modern welfare economies is public consumption, this implies that it is unlikely that project beta of an average public investment is zero (Baumstark and Gollier, 2014), as sometimes has been claimed (Arrow and Lind, 1970).

There is a seemingly close correspondence between the Ramsey and the CCAPMs in an economy where the consumer is a representative agent that therefore also can be seen as the social planner. However, the parameter γ has different interpretations in these models. In the Ramsey model $1/\gamma$ is the elasticity of intertemporal substitution, while in the CCAPM γ is the coefficient of relative risk aversion. These are separate aspects, though both relate to the curvature of utility functions.

The obvious difference between the ordinary Ramsey and CCAPMs, however, is that only CCAPM accounts for the fundamental fact that the future is not just happening at another time than the current but also that it is uncertain. In the standard framework where uncertainty is measured by standard deviation, the risk premium π is proportional to the variance of consumption per capita, which with historical data and plausible values of the coefficient of relative risk aversion implies a level of the risk premium that is substantially smaller than actual risk premia on asset markets (this is called "the equity premium puzzle"; Mehra and Prescott, 1985). Among several possible explanations, one is that investors have a strong aversion against risk in poor macroeconomic states, another is that the puzzle partly vanishes when fat-tailed properties of the probability distribution (i.e., low-probability disasters such as stock-market crashes or major political failures) are considered, and the third is that real consumption is more volatile than suggested by low-frequency expenditure data. A further aspect is the term perspective. The ex-post equity premium is considerably smaller when the risk-free investment alternative is taken to be a long-term sovereign bond until maturity than a short-term government bill. However, research on this issue has as of yet not come to a fully convincing resolution.

Approaches to Risk-Adjustment

Research on risk-adjustment of SDR is quite novel and many aspects remain to be considered. Two recent contributions give some guidance into how to derive the risk term in specific cases: the tail-hedge gamma and the elasticity-based beta.

The first of these approaches has been suggested in another contribution by Weitzman (2012, 2013). He assumes that the instantaneous net benefit of a single marginal investment project B_t can be decomposed as a linear combination of contemporary consumption, standardized with the expected value, and a project-specific random variable that is uncorrelated with consumption (which therefore can be made deterministic by diversification over a pool of projects). He defines the "real project gamma" as "the fraction of expected payoffs that on average is due to the uncertain macro-economy" (Weitzman, 2012, p. 15, italics in original). The discount rate for a project can then be computed as a weighted average of the rate of return on a risk-free asset r^f and risky equity r^m , where weights are given by the project-specific γ_t and the respective discount factors.

$$r_t = -\frac{1}{t} \ln \left[(1 - \gamma_t) e^{-r^f t} + \gamma_t e^{-r^m t} \right]. \quad (7)$$

This means that the short-term risk-adjusted rate is a gamma-weighted average of the two discount rates and then eventually falls down to the risk-free rate. Weitzman (2013) does not indicate how the gamma can be empirically estimated. This issue has later been explored by others. A useful result of that research (Mantolos and Hultkrantz, 2018) is that if projects returns and aggregate consumption follow Brownian motion and are co-integrated then gamma is unity, that is, the discount rate equals the equity rate.

The second approach has been developed by Gollier and Cherbonnier (2018). They address the task of estimating CCAPM beta assuming that investments, for instance in infrastructure, enable operation and consumption of services (transportation) that are governed by demand and supply relations that are log-linear in price and income, thus have constant elasticities. On the demand side, the consumers' instantaneous benefit of the service is:

$$B = \vartheta C^{\rho} \frac{x^{1-\alpha}}{1-\alpha}, \quad (8)$$

which gives the following demand function.

$$\ln x^d = \frac{1}{\alpha} \ln \vartheta + \frac{\rho}{\alpha} \ln C - \frac{1}{\alpha} \ln p, \quad (9)$$

where x^d is demand, C is income (or aggregate consumption), p is price, $\frac{\rho}{\alpha}$ is the income elasticity of demand, ρ is the income elasticity of the consumer valuation (willingness to pay), and $-\frac{1}{\alpha}$ is the price elasticity ($\alpha < 1$). Assuming that growth of C follows a Brownian motion with a linear trend, and variable cost follows Brownian motion, the CCAPM beta can be determined in the three special cases:

- A (perfectly inelastic supply): constant beta, $\beta = \rho$
- B (perfectly elastic supply): constant beta, $\beta = \frac{\rho}{\alpha}$
- C (limited capacity): declining beta, from $\beta = \rho$ to $\beta = \frac{\rho}{\alpha}$

In interpreting this, it should first be observed that, in a growing economy, a large-income elasticity of benefits means, on the one hand, a rapid growth of the nominal (undiscounted) benefits, and, on the other hand, a high beta, and therefore a high risk-adjusted discount rate. The net effect of an increase of this elasticity on the present value can therefore go in either direction.

The polar cases A and B have different implications for how income growth affects quantity and price of the service. In case B, with perfectly elastic supply, price will stay constant but the quantity demanded will vary proportionally to income, at a degree equal to the income elasticity of demand. In case A, quantity will be constant but price will vary with income, with the income elasticity of the willingness to pay as the factor of proportionality. Since $\alpha < 1$ the income elasticity of demand is by assumption in this model higher than the income elasticity of the willingness to pay. Thus, in the combined C case, which for instance could represent a transportation infrastructure investment where services are supplied at a constant marginal cost up to the capacity limit, beta for short maturities is close to the demand elasticity with respect to income and for long maturities falls to the willingness to pay elasticity with respect to income.

Empirical Parameters

Market Rates

Following Piketty's (2014) influential book, several studies have collected historical data on rates-of-return on various types of capital assets. For instance, Jordà et al. (2019) report long-run return on government bonds, short-term bills, equities, and housing in advanced economies from 1870, while Meyer et al. (2019) map returns on sovereign bonds for many countries traded in New York and London after the battle of Waterloo in 1815. Major findings by Jordà et al. (2019) are that real safe returns in peacetime periods have been low, in the 1%–3% range, but quite volatile, while the ex-post risk premium has been stable at about 4%–5%. That means that the risky rate on both equities and housing has also been quite stable averaging between 6% and 8%.

A large range of CAPM betas for transportation investment has been estimated for various modes, countries, and time periods. On the US market, values are regularly reported by "The iShares Transportation Average ETF" that seeks to track the investment results of an index composed of US equities in the transportation sector, with exposure to US airline, railroad, and trucking companies. This average beta usually exceeds unity. Krüger (2012) has used long time-series data for Sweden to compare transportation modes at various time scales. He found that traffic demand on railroad is more GDP-sensitive than demand for road, and freight transportation is generally more GDP-sensitive than passenger transportation. Also, traffic demand variance and GDP-sensitivity decrease with the length of time scale considered.

Ramsey-Equation Parameters

The first term of the Ramsey equation can conceptually be split in three components: pure impatience of the current generation, pure preference across generations, and the probability of extinction of the human race (for instance, because of a comet hitting planet earth). A recent survey among experts on their suggestions (Drupp et al., 2018) shows mean and median value of this parameter at 1% and 0.5%, respectively. The second term is g , the expected relative growth of consumption, or GDP per head, times γ , the elasticity

of the marginal utility of consumption. The latter parameter can be considered as reflecting both inter- and intra-generation inequality aversions. Commonly used levels of this parameter are about 1–2. Thus, a typical “Ramsey rate” without consideration of the risk cost, assuming a 1.5% growth rate, could be $0.5 + 1.5\% \times 1.5\% = 2.75\%$.

Risk-Adjusted Rates

The tail-hedge discounting model has been applied for estimation of risk-adjusted SDRs for transport infrastructure planning on historical time-series data in Sweden by [Hultkrantz et al. \(2014\)](#) and in Germany by [Goldmann \(2019\)](#). The indicated risk terms in proportion to the average equity premium are higher in Sweden (SE) than in Germany (DE) and in both countries lower for rail passenger travel than for road transportation or rail freight. For an average equity premium of 4.5% the short-term risk premia would be 2.6% (SE) and 1.0% (DE) for rail passenger travel and 4.2% (SE) and 3.6% (DE) for the other categories. The corresponding numbers for the 50 years maturity are 2.5% (SE) and 0.5% (DE) (rail passenger) and 3.7% (SE) and 1.7% (DE) (other).

Introduction

A widely used summary measure of a consumer product's demand sensitivity to changes in its price and other attributes and also in the price and attributes of rival products is provided by what are termed elasticities. These represent the proportionate change in the demand for a product in response to a proportionate change in some continuous attribute, such as price or journey time. Analogous measures can be calculated after a unit change in some categorical variable, such as the need to interchange vehicles or the introduction of new vehicles, and these are sometimes termed elasticity-type measures.

Elasticities are widely used across consumer markets because they have the attractive properties of being transparent, interpretable, transferable, and easy to apply in demand forecasting. The transport market is no different, with demand elasticities used for planning and economic appraisal purposes, although what is perhaps an unusual feature of the transport market is that nonprice related attributes, such as journey time, access/egress time, reliability and comfort, and in the case of public transport service frequency, crowding and the need to change vehicles, attract as much if not more attention as price. For standard consumer products, it is price elasticity which tends to dominate in conventional economic theory. Within transport, price can take various forms, such as fuel cost, parking cost, toll charge, and public transport fare with likely different degrees of sensitivity.

The key determinants of elasticity values, other things being equal, are likely to be:

- the availability of substitutes;
- the time period (short-, medium-, long-term) over which changes are measured;
- the need for the trip—at all, by a particular mode, to a particular destination; and
- the proportion of income spent on the trip.

These apply equally to: own-elasticities, which measure change in demand for a product when some attribute of that product changes; and cross-elasticities, which measure change in demand for a product when some attribute of a different product changes. Of course, for many practical purposes, the latter may be zero; it is unlikely that the demand for bus trips in Stockholm depends on the price of meatballs. It might therefore be expected that in many cases, cross-elasticities will be (absolutely) small, since they capture only part of the response of a change in a product attribute.

Demand elasticities in the transport market therefore cover a wide range of attributes and have long been one of the most important parameters of transport planning. Of specific interest here are cross-elasticities which deal with competition between different products which might, for example, be alternative modes of transport, routes, destinations, operators, or ticket types. And from these various choice contexts, we here address competition between modes.

Cross-elasticities between modes are important for a number of reasons:

- Policy interventions on the grounds of environmental, congestion, and energy considerations are critically dependent upon forecasting modal transfer.
- Strategic demand forecasting by public transport operators requires that the effects of changes in the prices and service quality of competing modes are identified. They have increasingly recognized that in ever more competitive and deregulated environments it is not sufficient to focus only on their own demand but also on what can be attracted from other modes and the threats posed by substitute modes.

- Competition policy and antitrust policy, particularly considering ownership/control of potentially competing modes or routes of transport such as long-distance rail versus intercity coach.
- To operationalize the theory of second-best pricing, whether this be to adjust the price of one mode in order to mitigate the failure to internalize an externality in a related mode (for example, reduce bus fares to offset the failure to introduce road pricing) or to adjust the prices of different modes (bus, rail, tram) by different proportions in order to meet an overall budget constraint for the transit operator.

Essentially, travelers now have more choices than ever before and where realistic choices exist then cross-elasticities are relevant.

Cross-Elasticity Relationships

Cross-elasticities cannot be understood in isolation. But they are also notoriously tricky to find. The purpose of this section is to examine the theoretical relationships between own- and cross-elasticities in order to see how cross-elasticity values may be deduced using the evidence on own-elasticities which is available or to see how such relationships can be used to enhance the accuracy of their estimation.

Inter-modal cross-elasticities denote the proportionate change in the demand for a mode after a proportionate change in some variable that characterizes the attractiveness of a substitute mode. Larger cross-elasticities between a pair of modes indicate greater substitutability, all other things equal.

Cross-elasticities play a central role in the economic theory of travel demand, and there are a number of relationships that exist that are important in understanding, estimating, and deducing cross-elasticities and indeed ensuring consistency of empirical evidence with economic theory. They also demonstrate clearly a key feature of cross-elasticities that they can be expected to be highly sensitive to market conditions. It is one thing to use constant own-elasticities, which is often countenanced in transport demand forecasting even though the basis for it is sometimes questionable, but it is far less acceptable to adopt constant cross-elasticities as the various relationships set out below indicate.

First, the Slutsky symmetry equation expresses the relationship between two price cross-elasticities as:

$$\eta_{ij} = \eta_{ji} \cdot \frac{D_j P_j}{D_i P_i}, \quad (1)$$

where η is the cross-elasticity between two modes i and j , D denotes their respective levels of demand and P their prices. Strictly, this rule applies to income compensated elasticities. For ordinary (Marshallian) elasticities, additional terms including the income elasticity are required. However, when the income share of expenditure is small, as will often be the case, the difference between compensated and ordinary elasticities is small, certainly at the level of the individual urban trip. In other cases, this approximation may not be valid, for example the cost of an annual public transport season ticket versus the cost of maintaining a private vehicle for commuting purposes. The prospect of large variations in cross-elasticities is here apparent.

Second, the Cournot aggregation condition specifies that:

$$\sum_{j=1}^n \omega_j \eta_{ji} + \omega_i = 0. \quad (2)$$

This states that the sum of cross-elasticities weighted by the budget share ω plus the budget share of mode i should be zero. This relationship implies that cross-elasticities are bigger (smaller) when there are fewer (more) competitive alternatives and that cross-elasticities are bigger (smaller) when the mode has a major (minor) share of expenditure and, if similar prices, trips.

The usefulness of this result is helping to fill in gaps when some, but not all, of the elasticities are known, to confirm/adjust/make consistent a set of own-elasticities and cross-elasticities. It can also be imposed as a condition as part of the estimation process to enhance accuracy and ensure consistency of results.

Third, the homogeneity condition, whereupon demand functions are homogenous of degree zero in prices and incomes. This is essentially a formal statement of the absence of money illusion. Across n modes, this is specified as:

$$\sum_{j=1}^n \eta_{ij} + \eta_{ii} = 0. \quad (3)$$

This requires that the sum of the own elasticities and cross-elasticities for a mode and its income elasticity (η_{ii}) equal zero. It is unclear whether this can ever, in restricted circumstances, be applied to time; certainly, it cannot apply to time in the long run for an individual.

These three relationships rely upon the assumptions of neo-classical micro-economic theory and, since they apply at the individual level, we must assume that aggregate behavior reflects that of the typical individual. There is though a relationship between cross and own elasticities that is true by definition:

$$\eta_{ij} = -\eta_{ji} \frac{D_j}{D_i} \cdot \delta_{ji}, \quad (4)$$

where additionally δ_{ji} is the diversion factor denoting the proportion of users of mode j who switch to or are attracted from mode i . This applies to all variables and not just price and is therefore particularly important as a means of deducing cross-elasticities where there is little or no evidence.

If we believe that a unit change in generalized cost has the same impact regardless of whether it stems from a change in price or journey time or any other variable, which many regard to be a reasonable pragmatic assumption, then the following relationship between, say, time (η_{ijt}) and price (η_{ijp}) cross-elasticities exists:

$$\eta_{ijt} = \eta_{ijp} \frac{vT_j}{P_j}, \quad (5)$$

where T denotes journey time and v is the value of time. This can be extended to other cross-elasticities that enter the generalized cost term such as walk time, headway or late time. Given that the literature on cross-elasticities tends to be limited, and might particularly be so for variables which tend not to vary much such as bus and car journey times or access times to train, this allows cross-elasticities to be deduced from evidence that does exist, with price most likely being the reference cross-elasticity used.

Hence we conclude that cross-elasticities:

- are intrinsically variable;
- should observe specific relationships (in some cases approximately); and
- can be deduced.

Estimating Inter-Modal Cross-Elasticities

We can distinguish between estimation models that are based on aggregate data, which is the collective outcome of decision makers' choices, or where the unit of observation is those individual choices. We here provide a *brief* account of the key features of the different approaches

Aggregate Demand Models

Such models are based on aggregates of modal demand, which are the outcome of choices made by the relevant population of individuals. They can operate at different levels of aggregation. At one extreme, the number of trips by a specific mode might be recorded at the national level, such as the number of car kilometers per year or international departures. More granularity and indeed more data are provided by demand recorded at the route level, such as the number of bus trips on different corridors or number of rail trips between various stations, while the least aggregated form is the total number of trips made by a household or individual in a specific period.

The models are almost invariably based on secondary data, such as those obtained from public accounts, traffic counts, national travel surveys, or the sales data of transport operators, although survey data might be collected specifically for the purposes of modeling demand at the aggregate level. Secondary data are often limited in behavioral detail, such as breakdowns of the purposes of the journeys or journey length distributions, but nonetheless provides a firm basis in actual behavior.

The models tend to be single equation, dealing with the demand for a specific mode, and to be based on data with a time series element. Variations in demand over time are explained as a function of the price, journey time and other relevant features of the mode in question, the levels of external factors such as income, population and employment which are key drivers of travel behavior, and the price and characteristics of substitute modes.

In general, aggregate models contain limited allowance for cross-elasticities, partly because obtaining reliable historic data on the times, prices, and service quality features of rival modes is not straightforward, and makes little use of the relationships set out in the second section. There can also be problems of large correlations between variables and limited variations in others, which compounds the difficulties of "hard to estimate" cross-elasticities given they tend to be relatively small. Where cross-elasticities are successfully estimated, they tend to be a single term and do not exhibit the spatial and indeed temporal variations that would be expected from the relationships earlier.

An approach, which overcomes some of these difficulties, is to explain the market shares of different modes at a specific point in time in terms of their prices, journey times, and other features. There is then no need to source historic data while spatial variations in prices and journeys times generally exceed temporal variations. However, it is rare that sufficient market share data are available for modeling purposes while market share can vary due variations in the size of the total market for reason not connected with the variables in the mode choice model. The discrete choice models discussed later provide better possibilities for investigating mode choice.

Alternatively, we might explicitly harness the relationships of economic theory in developing an empirical understanding of the demand for different modes and the competition between them. These could take the form of a set of inter-related demand functions covering the various modes, rather than a single mode specific demand function, whereupon the relationship among cross-elasticities and between cross- and own-elasticities can be used both to assist the challenges of estimating relatively small and inherently variables cross-elasticities and also ensure consistency between estimated values and economic theory. Unfortunately, there has been very little use made of such methods in the transport market.

Discrete Choice Models

In contrast to the analysis of behavioral aggregates, there is a rich strand of research that examines the choices made at the level of the decision maker, typically the individual, and mode choice is the most commonly examined real-world travel choice context. Explaining choices between modes naturally provides cross-elasticity estimates as well as other means of forecasting competition.

Such models take the market size as given and aim to explain individuals' choices as a function of the times, prices, and other relevant features of different modes. The parameters estimated to explain how time and price and other factors impact on choice allow both own and cross-elasticities to be estimated, although the former account only for the mode choice element and must be supplemented with evidence on how changes in prices and times lead to changes in the number of trips.

The models can be estimated to actual choices made in the market place, and which are referred to as revealed preference (RP) data. In contrast with aggregate methods, discrete choice methods can exploit what is typically referred to as Stated Preference (SP) data, where individuals are presented with a series of different hypothetical mode choice scenarios and asked to state which mode they would prefer.

The attractions of RP data are that it reflects what decision makers actually do, but then it is limited by what the market has to offer which might not provide a firm basis for the analysis of how price, time, and other factors impact upon mode choice.

The attractions of SP data are to a greater extent the mirror image; respondents are not committed to behave in accordance with their stated preferences but the control of the experimental context means that the data problems that can afflict RP methods are avoided and multiple choice observations per decision maker are collected.

Both methods have the attraction of being able to undertake detailed segmentation by key variables because of the availability of individual level data. So, for example, they allow cross-elasticity estimates to be obtained by journey purpose and journey distance, which can be readily implemented in application models.

A key feature of discrete choice models, again in stark contrast to the aggregate models, is that the elasticity terms are inherently variable, depending upon market share and generally the levels of the variable in question and thus not obviously immediately transferable between situations. The models calibrated need to be specified carefully in order to ensure that the resulting elasticities are consistent with economic theory; this is not always done. Mode share elasticities are very different in nature when compared with ordinary (Marshallian) or income-compensated (Hicksian) elasticities of the type more conventionally used by economists. While mode share elasticities can be derived from Marshallian or Hicksian elasticities, the reverse is in general not possible.

While discrete choice models have numerous attractions in principle, in practice SP evidence dominates and models estimated to such data tend to provide what is often regarded to be large sensitivity in the demand for one mode in response to changes on another mode. There are also issues involved in relating changes in practice to individuals' perceptions while, unlike aggregate models based on time series data, the models do not readily incorporate a dynamic aspect and lags in behavioral response.

Deduced Cross-Elasticities

Given the challenges involved in estimating cross-elasticities, and indeed the time and resources required, there has been increasing use in recent years of deducing cross-elasticities. This uses Eq. (4) earlier which consists of the relevant own-elasticity, relative demand levels, and diversion factors.

Own-elasticities are typically obtained from official guidance, conventional wisdom, or the wealth of evidence covered in the numerous reviews of own-elasticities that now exist in the literature. Ideally, these should be explicitly long run, but with some indication of the short-run impact and the path to the long-run effect.

Relative demand levels can be obtained from national travel surveys, which are conducted in many countries, and are sometimes contained in census data. Other sources might be local transportation models and studies as well as bespoke surveys and indeed "informed guesstimates." It can be more difficult to obtain robust estimates of relative demand as the level of spatial disaggregation becomes more detailed; aggregation over large areas smooths out much of the inherent variability (as is, of course, common with averaging and, indeed, in most cases, an attractive feature).

Diversion factor evidence can be obtained from reviews, as reported in (10031 – Elasticities for Travel Demand), but it might also be practical to undertake surveys of travelers to determine their best alternatives. The latter has attractions given that diversion factors can be expected to vary across contexts, not least as the relative attractiveness of different modes varies, although the issue of spatial detail again arises. In some circumstances, informed guesstimates may well be sufficient.

A further attraction of this approach of deducing cross-elasticities is that it allows context specific cross-elasticities to be used in forecasting and appraisal while also aiming for consistency with economic theory.

Cross-Elasticity Conventional Wisdom

The evidence on cross-elasticities is much less secure than that on own-price elasticities since it has been derived from fewer sources and is much more location-specific. Toner et al. (1995) found very small cross-elasticities of demand for car with respect to rail price, mostly under 0.1, for the inter-urban market. Larger cross-elasticities were found for rail demand with respect to car travel time in the business market. Dargay et al. (2010) found some evidence of larger cross-elasticities, particularly between rail and coach and for rail

and coach demand with respect to price of car, up to 0.5 being common. Cross-elasticities of demand for car with respect to public transport were, though, still very small.

In the urban context, [Lewis \(1977\)](#) reports a car use elasticity with respect to public transport prices of 0.06 in the peak in London. [Kemp \(1973\)](#) has a figure of 0.14 from his work in Boston, again for car use with respect to public transport price. [Glaister and Lewis \(1978\)](#) derive cross-elasticities of peak car use with respect to peak and off-peak bus and rail fares of approximately zero in London. [Dodgson \(1990\)](#) reports on an elasticity of bus use with respect to underground fare in London of 0.1, but a much lower elasticity with respect to surface rail fare. He cites a much higher elasticity of bus use with respect to car costs of 0.62, based on work in six towns and cities. This seemingly large figure is probably because of the relatively minor role played by bus; relatively few car drivers switch, but they are large relative to the number of existing bus users. [Goodwin \(1992\)](#) obtains an average public transport use elasticity with respect to car cost of 0.34.

[Rietveld and Daniel \(2004\)](#) find low cross-elasticity between bicycle and car, and that bicycle mainly competes with public transport. [Wardman et al. \(2007\)](#) forecast that a set of political instruments to double cycling volumes only reduces car traffic by 5%. [Börjesson and Eliasson \(2013\)](#) find similar results that only 13% of Stockholm cyclists quote car as their second-choice mode. The 1991 introduction of the Oslo toll road scheme generated some research on the effect of car user payment on public transport. The effect was deemed negligible ([Ramjerdi et al., 2004](#)).

The published evidence on cross-elasticities is thus sparse, difficult to apply, since it is location-specific, depending crucially on the mode shares in the different cities, and not obviously susceptible to a “conventional wisdom” approach.

Illustrative Cross-Elasticities

Prior to setting out some illustrative cross-elasticities, we make two important points. First, the amount of empirical evidence relating to cross-elasticities tends to be much less than for own elasticities and indeed review studies of the former are far less common than for the latter. Second, while it has been pointed out that cross-elasticities are inherently variable parameters, despite this cross-elasticities are constant in some model estimations and indeed in appraisal recommendations.

The focus here is on the output of a major review of international cross-elasticity evidence and upon deducing cross-elasticities given the challenges of estimation. A feature of both discussions is the inherent variability of cross-elasticities.

Review Evidence on Cross-Elasticities

The most extensive review of cross-elasticity evidence so far undertaken covered 1096 values from 93 studies and 18 countries spanning the years 1961 to 2017 ([Wardman et al., 2018](#)). The regression based meta-analysis explained variations in cross-elasticities according to a number of factors, and key among them were the transport variable in question, combination of mode affected and mode altered, method of analysis, whether the cross-elasticity was explicitly short run, long run or indeterminate, journey purpose, journey length, a time trend, and mode share. The mode share term essentially replicated the D_j/D_i term of Eq. (4).

Table 1 reports illustrative cross-elasticities implied by the meta-model for a range of circumstances. This is done for cost (fuel or fare as appropriate) and time cross-elasticities between the main modes of car, bus, and rail, primarily for a variety of urban trip features but with extension to inter-urban trips, and for the three main journey purposes. The implied cross-elasticities are for 2017 and are generally long run but with some short-run variants.

A key feature of the meta-model is the impact of relative demand as expected from theory. The figures used in **Table 1** are the approximate 25th, 50th, and 75th percentiles of relative demand for urban trips in the estimation data set. These figures are 4, 7 and 14 for D_C/D_B , 0.4, 0.9 and 1.2 for D_R/D_B , and 3, 10 and 16 for D_C/D_R . Of course, a more extreme set of values could be used, such as a very high ratio of D_R/D_B and a very low ratio of D_C/D_R for commuting trips into major metropolis. Implied cross-elasticities are also provided for inter-urban trips but only for the mean ratios, which were 21 for D_C/D_B , 5 for D_R/D_B , and 4 for D_C/D_R .

The illustrative cross-elasticities seem sensible, covering a large range in line with expectations but without implying extreme cross-elasticities that would cast doubts upon the estimated meta-model; there is no guarantee of such desirable properties from meta-models!

The model can be used to provide cross-elasticities customized to specific contexts. As expected, the implied cross-elasticities exhibit a considerable amount of variation, not only according to the relative demand levels but also between time and cost, short run and long run, urban and inter-urban trips, and commuting, leisure and business travel.

Car cross-elasticities tend to be low, reflecting the generally large market share of car, and are larger for time than cost. The public transport cross-elasticities are also larger for time than cost, in some cases very much so. These differentials have implications for policy measures aimed at inducing mode switch. The long-run cross-elasticities are noticeably larger than the short run, with a ratio of around 2.4., and the inter-urban cross-elasticities indicate a generally much stronger degree of competition between modes than for urban trips.

Deducing Cross-Elasticities

Since 1986, the *Passenger Demand Forecasting Handbook* (PDFH) has been unique in the world in providing a framework and associated parameters that are recommended for use in Great Britain for forecasting the effects of changes in a wide range of variables.

Table 1 Illustrative cross-elasticities implied by meta-model.

	Relative demand			Cost (Car fuel or public transport fare)						In-vehicle time					
	D_O/D_B	D_R/D_B	D_O/D_R	Bus:Car	Bus:Rail	Rail:Car	Rail:Bus	Car:Bus	Car:Rail	Bus:Car	Bus:Rail	Rail:Car	Rail:Bus	Car:Bus	Car:Rail

Nonetheless, prior to the 4th edition in 2002 there was no accounting for competition from other modes in the form of cross-elasticities. That edition introduced recommended cross-elasticities between rail and the competing modes of car, bus, and air, largely stimulated by the previously unaccounted for effects of increases in fuel prices and car congestion on rail demand. This was an advance but industry analysts recognized that cross-elasticities are context dependent, whereupon the next edition (4.1) in 2005 provided a further advance by including a recommendation to deduce cross-elasticities using Eq. (4).

Car costs are a potentially important driver of rail demand not only because car is the main competitor to rail in many contexts in Great Britain but because PDFH recommends some quite high cross-elasticities to car cost in the range 0.2 to 0.4 and fuel prices have a history of varying and indeed are forecast to fall somewhat in the medium term.

While PDFH still recommends “overall” cross-elasticities by a limited number of flow types, Table 2 demonstrates how the deduced cross-elasticity of rail demand with respect to car fuel cost using Eq. (4) can vary considerably.

The long-run car fuel cost own-elasticities (η_{CC}) are taken from official Department for Transport recommendations contained in webTAG, and are -0.1 for business, -0.3 for commuting, and -0.4 for other trips. The diversion factors (δ_{CR}) are taken from a review of such evidence and reported in (10031 – Elasticities for Travel Demand) and are 0.12 for urban trips and 0.65 for inter-urban trips. While the own-elasticities might vary by distance and other factors, and the diversion factors can be expected to vary with market conditions among other things, evidence on such variation is lacking or not clear-cut. Evidence on the relative demand of car and rail (D_C/D_R) for the specific flows in question was taken from the National Travel Survey, which provides a representative account of travel behavior in Great Britain. Finally, for leisure trips, we allow for car occupancy of 1.7 when deducing the implied transfer to rail.

There are instances where the cross-elasticities are very low, generally for trips of any purpose into Central London where rail dominates given high levels of traffic congestion, the congestion charge and the high costs and limited availability of parking. When extended to Inner and Greater London, rail is less dominant since these car related problems are less and hence the cross-elasticities increase, particularly for other trips.

For longer distance trips over 100 miles not involving London, rail is in a weaker position and the cross-elasticities are accordingly higher although even here rail is in a stronger position, presumably because of the distances involved, than for the longer distances trips that are between 20 and 100 miles where we observe some very large cross-elasticities as is the case for other trips for short distance trips outside London. Car is in a much stronger position, in general, for trips not involving London.

Of course, cross-elasticities will vary across specific flows within any of these categories as market conditions vary. But the figures show much more variation than PDFH recommends.

While the example here is based around car cost cross-elasticities, the procedure readily extends to other variables and to competition between other modes therefore enabling a full set of context specific cross-elasticities to be obtained for policy and appraisal purposes.

Table 2 Illustrative cross-elasticities of rail demand with respect to fuel cost.

Flow type	Purpose	η_{CC}	δ_{CR}	D_C/D_R	η_{CR}
Long distance to central London ≤ 150 miles	Business	-0.1	0.65	0.21	0.01
	Other	-0.4	0.65	0.24	0.11
Long distance to central London > 150 miles	Business	-0.1	0.65	0.18	0.01
	Other	-0.4	0.65	0.11	0.05
Long distance to central London	Business	-0.1	0.65	0.21	0.01
	Other	-0.4	0.65	0.20	0.09
Long distance to greater London	Business	-0.1	0.65	0.56	0.04
	Other	-0.4	0.65	0.95	0.42
Non-London long > 100 miles	Business	-0.1	0.65	3.79	0.25
	Other	-0.4	0.65	1.37	0.61
Non-London long 21–100 miles	Business	-0.1	0.65	9.97	0.65
	Other	-0.4	0.65	2.44	1.08
Non-London < 20 miles within urban areas	Commute	-0.3	0.12	4.66	0.17
	Business	-0.1	0.12	9.00	0.11
	Other	-0.4	0.12	9.99	0.82
London travel card area	Commute	-0.3	0.12	0.92	0.03
	Business	-0.1	0.12	1.63	0.02
	Other	-0.4	0.12	2.62	0.22
South east to central London	Commute	-0.3	0.65	0.04	0.01
	Business	-0.1	0.65	0.28	0.02
	Other	-0.4	0.65	0.16	0.07
South east to central and inner London	Commute	-0.3	0.65	0.16	0.03
	Business	-0.1	0.65	0.53	0.03
	Other	-0.4	0.65	0.47	0.21

Conclusions

Cross-elasticities are important for a range of policy evaluations: for governments seeking to effect mode shift from more- to less-polluting modes; for operators seeking to forecast demand as prices and quality attributes of various modes change; for assessing the efficiency, in a second-best world, of transport prices.

In this chapter, we have introduced some relationships between own- and cross-elasticities. These relationships can be used: to constrain econometric analysis to enhance the accuracy of estimation; to assess the plausibility of elasticities estimated using econometric models; and to fill in gaps where some elasticities are known but others are not. These relationships should always hold for price variables, but only some are relevant for time and quality variables.

Some headline results from economic reasoning are as follows:

- The own-price elasticity should be negative and can be absolutely small or large in magnitude.
- The cross-elasticities should all be positive (for substitute goods) and smaller in magnitude than the own price elasticity.
- The more cross-elasticities there are (i.e. the more related products there are; these related products can be competing modes along the line of route or even away from the line of route. As with all analysis of competition, market definition and geographic scope are important determinants of the range of feasible alternatives), the smaller each cross-elasticity should be on average for a given own price elasticity; and/or the bigger in magnitude the own price elasticity.

In general, unless a detailed bespoke study is undertaken for a particular place/flow, we recommend deducing cross-elasticities since they are so highly context-specific. Simply transferring cross-elasticities from one situation to another is difficult unless the competitive situation and the existing mode shares are very similar, although the meta-analysis reported here does facilitate transfer by allowing for mode share effects. But to make these deductions securely, much more evidence is needed on diversion factors—more information but also how these vary by typical factors like purpose and distance, and more on the effect of the competitive situation. It is necessary to be careful when defining market shares to ensure spatial consistency.

This blend of data analysis and economic theory seems to us the most promising way to estimate a full set of own- and cross-elasticities for transport given the inherent difficulties in most contexts of simply estimating such things econometrically.

Introduction

Roads are the scarce resource and their usage is a source of important external costs (congestion, emissions). Road pricing allows efficient usage of the available transportation infrastructure. First-best congestion pricing is a pricing scheme that maximizes social benefit, defined as the difference between users benefit and the social cost. When only congestion cost is considered, the social cost is equal to the aggregate users cost. But, when wider impacts, like emissions, are taken into account, the social cost is larger than the aggregate users cost since a wider population is concerned by the externality. Road pricing has now been implemented in several metropolitan areas around the world, and many others are considering its introduction under urban transportation reforms. First-best congestion pricing is rather a theoretical policy which describes the maximum attainable cost reduction from a transportation pricing reforms. It is specific to each trip and requires the availability of detailed data, which is usually difficult to obtain. Second-best policies, which require less information, are usually considered easier to implement in practice, but recent technological advances in information technologies and the availability of autonomous cars can raise interest in the implementation of first-best congestion pricing. Indeed, geolocation of vehicles and detailed description of the trips with respect to spatial (exact route) and temporal patterns (departure and arrival times) became much easier to obtain.

The interest of economists in congestion pricing is rooted in the work of Arthur Pigou who explained how the divergence between private and social costs could be a source of economic inefficiency. The advanced formulation and analysis of problems dealing with congestion pricing in transportation economics followed the progress made on two fundamental themes. The first one is the good and wide understanding of the equilibrium concept through the well-known Wardrop equilibrium (named after John Glen Wardrop). Consider a network where users have several possible routes to go from a given origin to a given destination. In a Wardrop equilibrium, travel costs on all used routes are equal and are smaller than travel costs on the unused routes. While this idea of equilibrium was expressed by Knight in the 1920s, it became widespread in the analysis of traffic equilibrium after the formulation by Wardrop in the early 1950s. It became important to develop analytical approaches to compute the Wardrop equilibrium, and this is where the contributions of authors like Martin Beckmann stand. They worked on the formulation and solution procedures of network equilibrium and the quantitative evaluation of the welfare loss due to congestion. The second important step is due to the contributions of William Vickrey and his seminal work on dynamic congestion, which brought an important community of researchers to develop modern dynamic models (Arnott et al., 1990).

This chapter is organized as follows. The section Static models with a single road is devoted to static models. We first consider the case of a single link and then extend the discussion, in section Road networks, to the case of a road network. In Section Dynamic models we consider dynamic congestion and explore the bottleneck model. We then conclude with some comments.

Static Models with a Single Road

Consider a road link with a fixed capacity. Each user entering and crossing this link gets a benefit with a magnitude that depends on the user's characteristics, the trip purpose, and the other transportation alternatives available to reach the destination. The monetary value of this benefit can be interpreted as the willingness to pay of using the road link. Consider a group of several users and sort them in a decreasing order with respect to the values of their willingness to pay. We obtain a demand function for using the road link. At the same time, each user entering the link slows down travel speed. When traffic flow is significantly below road capacity the impact is small, but it becomes important as traffic flow reaches and exceeds road capacity. So, user cost increases as the number of users increases. As long as there are users with a willingness to pay that exceed

Table 1 User equilibrium and optimum. SMC is the social marginal cost, e and o exponents refer to equilibrium and optimum levels, respectively

15	24	570	40	68	600	-30

the user cost, traffic flows increases. Since users are sorted in decreasing order with respect to their willingness to pay, the equilibrium is reached when both quantities are equal; the last user who enters the road link has a willingness to pay which is equal to the average user cost. Users with smaller willingness to pay will not use the road link, they either use another alternative (other route or other mode) or they simply do not make the trip, which is likely to occur when the purpose of the trip is not so urgent.

Each user then compares his benefit (willingness to pay) and the user cost to decide whether to use the road link or not. This individual process is the origin of an excessive congestion cost. Indeed, each user will rise the average travel cost, but will ignore the impact of this increase on the other users of the road link. Under free access, the equilibrium is characterized by an excessive use with large external costs. Imposing a toll for the users of the road can restore the optimum number of users.

A numerical example is useful as a first illustration. Table 1 develops a case where users, in Column (1), are sorted in decreasing order with respect to their benefit from using the road link, given in Column (2). As the number of users increases, the (average) user cost, given in column (4), increases. As long as there are users with a benefit higher than user cost traffic flows increase. Comparing values in columns (2) and (4) the equilibrium traffic volume is obtained with 11 users. The benefit of user 11 is equal to 32, which is equal to the user cost. User 12 will not enter the road link since his benefit is 30 and he faces a cost of 32. To see how this equilibrium solution compares to the optimum we need to compute the social benefit as a function of the number of users. In column (3) we give cumulative benefits, based on values in column (2), and in column (6) total cost is computed. The social benefit is the difference between these two quantities and is given in column (7). Social benefit reaches a maximum value with 7 users, which means that the equilibrium does not correspond to the social optimum.

To understand this result, it is useful to consider values in column (5) corresponding to the social marginal cost (SMC). The values of this column are computed as follows. For the first user, the SMC is equal to the user cost, 12 in this case. For the second user, the SMC is equal to the corresponding user cost, plus the impact of his entry on the user cost of the first user, or $14 + (14 - 12) \times 1 = 16$. For the third user, the SMC corresponds to the user cost plus the impact of his entry on the two former users, or $16 + (16 - 14) \times 2$. For the general case, the SMC of user n is $S_{mc}(n) = C(n) + (C(n) - C(n-1))(n-1)$. Since user cost $C(n)$ is increasing in n , $S_{mc}(n)$ is higher than $C(n)$. A simple computation shows that the SMC can be written in the following recursive form: $W(n) = W(n-1) + b(n) - S_{mc}(n)$.

So, a new entry will increase the social benefit when the benefit of the new user is higher than the corresponding social marginal cost. Since $S_{mc}(n)$ is higher than $C(n)$, the optimum number of users is smaller than the equilibrium number. From this expression of the social benefit, an entry is socially desirable when the benefit for the user is higher than the social marginal cost, not the private marginal cost. We see then why it is optimal to have 7 users in this road link.

Under free access the road link is overused. The optimum level can be reached by imposing a road toll equal to the difference between the SMC and the user cost: $S_{mc}(n^o) - C(n^o)$, where n^o denotes the optimum number of users. In this example, a toll equal to 14 will reduce users from 11 to 7, and then decentralizes the optimum.

This example can be developed in a continuous and more tractable version. Let n now denote a continuous measure of the number of users. The user benefit in Column (2) is then a decreasing smooth function $b(n)$ as illustrated in Fig. 1. The cumulative benefit in Column (3) is $B(n) = \int_0^n b(z) dz$ and corresponds to the area between the curve of $b(n)$ and the x -axis. The user cost $C(n)$ is an increasing function of n . The user equilibrium is obtained when the user benefit is equal to the (average) user cost. So, the equilibrium number of users, denoted n^e , satisfies $b(n^e) = C(n^e)$. Total welfare is the difference between $B(n)$ and total cost $nC(n)$, that

Figure 1 First-best congestion toll.

is, $W(n) = B(n) - nC(n)$. The optimum is reached when $W(n)$ is maximized over n (optimum traffic level), and the first-order condition is $W(n) = 0$. So, the optimum number of users, denoted n^o , satisfies

$$b(n^o) = \underbrace{C(n^o) + n^o C'(n^o)}_{S_{mc}(n^o)} \quad (1)$$

The equilibrium and optimum are given in **Fig. 1**, where the shaded area corresponds to the reduction of the net external cost when users are reduced from n^e to n^o . Net external cost is used to refer to the difference $nC(n) - b(n)$, that is, external costs net of the users benefits. The left hand side of eq. (1) is the benefit of user n^o and the right hand side is the sum of the private cost of the same user and the external marginal cost he generates. Both equilibrium level and the optimum level of users are uniquely defined, since $b(n)$ is decreasing and $C(n)$ is increasing. We also have $n^o \leq n^e$ because $C'(n)$ is positive, under the unpriced equilibrium there is an excessive use of the road. The decentralization of the optimum is possible through first-best congestion toll $\tau = n^o C'(n^o)$. From eq. (1), this toll will add the social cost to the private cost, or in other words it will internalize external costs.

For simple examples, a linear formulation of the user cost can be used, but for an empirical application a more realistic formulations are used. On a given road link, as we have mentioned above, travel time does not change so much when traffic flow is significantly below the road capacity, but increases substantially when traffic flow increases beyond critical level of capacity. The Bureau of Public roads (BPR) formulation is frequently used to express travel time as a function of traffic flow. In this case travel time on a given link is

$$t(n) = t_f \left(1 + a \left(\frac{n}{K} \right)^b \right), \quad (2)$$

where t_f is free-flow travel time, K the link capacity, and a and b positive parameters. In practice, $a = 0.15$ and $b = 4.0$ are the suggested values. For a given level of traffic flow, n , the nonmonetary part of travel cost is obtained by multiplying travel time [from Eq. (2)] by the value of time. The generalized travel time is then obtained by adding to this quantity the monetary travel cost. The example in **Fig. 1** has been constructed on the basis of this formulation.

Road Networks

The results obtained in the last section extend to road networks. We start with the case of a simple network to illustrate how the main purpose of the road toll is to reach an optimum distribution of users on the road network, and not necessarily to reduce urban mobility. We then comment on the case of a complex network where the computation of the optimum may be challenging.

A Simple Case

The analysis of external costs in a simple network provides a broader and more accurate description of the impacts of road pricing. In the case of a single link, a first-best congestion toll reduces traffic flow from n^e to n^o (**Fig. 1**), and it may be perceived as a policy against mobility of goods and passengers. Indeed, those who argue against road pricing frequently touch on similar arguments. By considering a network where each user chooses between several possible routes or transport modes it is described further that road pricing does not reduce the number of trips but rather induces an efficient use of the available infrastructure.

Figure 2 A simple network.

Consider the situation given in Fig. 2. A group of N drivers travel from A to B . There are two routes, a short but congested one, and a long and noncongested one (large capacity). To simplify the computation of the travel costs, we assume that only travel time matters. So, the objective of each driver is to reduce his travel time.

The shorter route is narrow and travel time significantly increases when the number of users increases. To consider a particular example, we assume that travel time on this route is $10 + n/5$ (expressed in minutes), where n is the number of users of the shorter route. The user may also travel through the longer route. This road has a large capacity and travel time does not significantly depend on the number of users and is assumed fixed and equal to 24 mins. At equilibrium, when both roads are used travel times are equal. For example, with $N = 100$ we obtain $n^e = 70$ confirming that most users choose the shorter route. The optimum number of users minimizes total cost, which is the sum of the total cost of users of the shorter road, equal to $n(10 + n/5)$, and the total cost of the users of the longer road $(N - n) \times 24$. Doing so, we easily find that total cost reaches a minimum when $n^o = 35$. In this case travel time (user cost) on the short road is 17 mins, while it is 24 mins on the longer route. Now, this optimum configuration can be decentralized by imposing a (first-best) congestion toll. The toll level can be adjusted so that only 35 drivers continue to use the short route. The corresponding value of the toll is equivalent to the monetary value of 3 mins.

By comparing the equilibrium and the optimum in this example, it is important to notice two key features in the solution. First, all users still make the trip and the first-best congestion toll is not harmful for anyone. No user has a travel cost higher than 24 mins since, for each user, the option of the longer route is always available. It is then clear that congestion toll does not prevent users from making their trips but induces an efficient distribution of flows over the network. Second, the revenue from the first-best congestion toll is equivalent to the benefit obtained by the users of the shorter route when their number is n^o . With this toll, all users have a generalized cost equal to 24, the same cost under equilibrium, but the government collects a toll revenue, which corresponds to the monetary value of the external costs produced under the unpriced regime.

Complex Networks

In a large network the computation of the equilibrium and the optimum become a challenging task. The network can be represented as a directed graph. Users are grouped with respect to their origin-destination pairs. Let g indicate the group of users, $g \in G$. Each group has one or several possible routes, a successive sequence of adjacent arcs, to travel from his origin to his destination. Let $c_l(u_l)$ denote the average user cost on link l when the number of users on that link is u_l . We have, $u_l = \sum_g u_l^g$, where u_l^g is the number of users from group g traversing link l .

The equilibrium conditions state that, for any group, generalized cost on all used routes are equal and are smaller than generalized costs on unused routes. The resulting set of equality and inequality constraints is not easy to solve, except in simple situations like the example examined in the last section. An alternative approach is to notice that the equilibrium problem is the solution of the nonlinear programming problem where the objective function given in Eq. (3) is minimized subject to the constraints that all users reach their destination and that the number of users on each link is nonnegative:

$$\min \sum_l \int_0^{u_l} c_l(z) dz. \quad (3)$$

Given a distribution of flows on the network, the total cost can be computed from $C(f) = \sum_l c_l(u_l) u_l$. The optimum is a distribution of flows $f = (u_l)$ that minimizes total cost $C(f)$. This problem can be solved as a multi-commodity problem, and it is clear that the equilibrium does not, in general, yield the optimum cost as we have shown in the simple network earlier. The optimum solution, which corresponds to an optimum distribution of flows on the network, can be decentralized through a link-specific toll similar to that described for the case of a single link. If we denote the user cost on link l by C_l and the number (flow) of users at the same link by u_l , Correa and Stier-Moses (2011) show that the social optimum is obtained when a toll

$$\tau_l = u_l C'_l(u_l) \quad (4)$$

is imposed on the user of link l . Notice that this is straightforward extension to the first-best corresponding to the case of a single link. The general idea underlying first-best congestion pricing is that each user is charged exactly the total external cost he generates.

Dynamic Models

In a dynamic model, not only travel time but also other features of the time pattern of the trip are explicitly taken into account. Users prefer a shorter travel time and avoid early or late arrivals (schedule delay) to work. They may prefer early to late arrivals. Modeling congestion in a dynamic framework is not an easy task and usually complex mathematical tools, like partial differential equations and optimal control problems with delays, are used to compute the equilibrium and the optimum (Arnott, 2013). The bottleneck model is an exception since it brings several properties entailing dynamic congestion while being mathematically tractable and intuitive. We describe here a simple version of the model that we use to derive time-varying tolls.

Let variable t denote time and consider a homogeneous group of users who prefer to arrive to destination at time t^* . We may think of the morning rush hour where t^* corresponds to the time when work starts. Generalized cost is the sum of travel time and schedule delay cost. Each unit of travel time costs α . A user arriving at $t < t^*$, early arrival, incurs a schedule delay cost equal $\beta(t^* - t)$. A user arriving at $t > t^*$, late arrival, incurs a schedule delay cost equal $\gamma(t - t^*)$. Commuters are assumed to prefer early to late arrivals. They also prefer higher travel time to later arrivals, but prefer earlier arrivals to higher travel time. These assumption are summarized in the condition $\beta < \alpha < \gamma$, and this model is frequently referred to as the $\alpha\beta\gamma$ -model.

Each user has to pass the bottleneck to reach the destination. The bottleneck has capacity of k vehicles per unit of time. When the number of users arrive at smaller rate the bottleneck is traversed instantly, otherwise k vehicles per unit of time exit the bottleneck. When arrivals to the bottleneck occur at a rate higher than k , the capacity is reached, a queue with first-in-first-out service forms. This is the only source of delays in the network. We then assume, without loss of generality, that the trip length is zero so that travel time is equal to the (possible) delay in the bottleneck. Notice that, in this simplified network, if there are no delays in the bottleneck travel time is zero. The population of the homogeneous users can be decomposed into two segments: those who arrive early and those who arrive late. Let $\tilde{t}$ denote the departure time of the user who arrives exactly on time.

The departure of the first user occurs at $t = t_0$ and the arrival of the last user occurs at $t = t_1$. Let $I = (t_0, t_1)$. Users departing at the endpoints of I do not incur delay to pass the bottleneck, but do incur a schedule delay cost. The total number of users is N , and since they all pass the bottleneck between t_0 and t_1 , we have $N = (t_1 - t_0)k$. We focus on an equilibrium where entry rates are constants and, respectively, equal to ρ_1 when $t < \tilde{t}$ and equal to ρ_2 when $t > \tilde{t}$. Given that users departing at t_0 and t_1 do not incur any delay and have the same generalized cost we have $\beta(t^* - t_0) = \gamma(t_1 - t^*)$. Using the fact that all users depart and arrive between t_0 and t_1 we have

$$t_0 = t^* - \frac{\gamma}{\beta + \gamma} \frac{N}{k}$$

$$t_1 = t^* + \frac{\gamma}{\beta + \gamma} \frac{N}{k}$$

Let $\delta = \beta\gamma(\beta + \gamma)$. These two users incur the same schedule delay cost

$$\beta \frac{\gamma}{\beta + \gamma} \frac{N}{k} = \gamma \frac{\gamma}{\beta + \gamma} \frac{N}{k} = \delta \frac{N}{k}$$

which is equal to their generalized cost. At equilibrium, this is the generalized cost for all users. At time t , the number of users in the queue is given by

$$n(t) = \begin{cases} (\rho_1 - k)(t - t_0), & \text{if } t_0 \leq t \leq \tilde{t} \\ (\rho_1 - k)(\tilde{t} - t_0) + (\rho_2 - k)(t - \tilde{t}), & \text{if } \tilde{t} < t < t_1. \end{cases} \quad (5)$$

The generalized cost for a user departing at time $t \in I$ is the sum of travel time cost and schedule delay cost. It is then given by

$$C(t) = \alpha \frac{n(t)}{k} + \beta \left(t^* - t_0 - \frac{n(t)}{k} \right) \quad (6)$$

since he has to wait for $n(t)$ users to pass the bottleneck. At equilibrium, all users have equal generalized costs. The equilibrium condition is then $C(t') = C(t'')$ for any $t', t'' \in I$. When this condition is applied for $t', t'' \leq \tilde{t}$ and $t', t'' > \tilde{t}$, respectively, it yields

$$\rho_1 = \frac{\alpha}{\alpha - \beta} k \quad \text{and} \quad \rho_2 = \frac{\alpha}{\alpha + \gamma} k. \quad (7)$$

So, at the first period, from t_0 to $\tilde{t}$ entries are higher than bottleneck capacity and a queue forms at a rate $\rho_1 - k > 0$ reaching its maximum at $t = \tilde{t}$. After this threshold, the queue starts to decrease at rate $\rho_2 - k < 0$ until it vanishes at time t_2 .

The delay caused by queuing is a source of welfare loss. This distortion can be removed, if each user arrives to the bottleneck exactly at the time where he exists the bottleneck under the equilibrium. In that case, there are no queuing and no delays. This departure pattern can be enforced through a time-varying toll given by

$$\tau(t) = \begin{cases} \beta(t - t_0) & \text{if } t \leq \tilde{t} \\ \gamma(t_1 - t) & \text{if } t > \tilde{t} \end{cases} \quad (8)$$

Figure 3 First-best time-varying toll.

This toll is highest during the peak period near t^* , and decreases as we move away from preferred arrival time. With this toll, travel cost of each user remains unchanged, but departure times are adjusted so that the arrival rate to the bottleneck is equal to its capacity k . First-best congestion toll removes the delays and the revenue it generates corresponds to the external cost generated under the unpriced equilibrium.

This problem is illustrated in [Fig. 3](#). For each t , the distance between the x -axis and the red curve corresponds to the schedule delay cost. The toll adds to this cost to reach a constant user cost equal to $\delta N/k$. The amount of the toll corresponds to the delay incurred by all the users in the bottleneck under unpriced equilibrium. The area above the red curve and below $\delta N/k$ line corresponds to the toll revenue (the shaded-area), which as we have noticed earlier, measures the external cost in the unpriced equilibrium. It is clear from [Fig. 3](#) that the triangle corresponding to waiting time cost (external cost) is half the total cost.

Finally, we show how dynamic tolls can be simply described through a two-player game. Each one of the two players wants to cross a limited capacity bridge. There are two time slots when crossing is possible, s_1 and s_2 , and both players prefer to cross at s_1 . Only one player can cross during each slot. Let b_i denote the benefit of crossing during slot $i = 1, 2$, and let $\bar{b} = b_1 - b_2$. If both players choose slot s_1 , only one, randomly chosen, crosses and the other waits for slot s_2 . This wait time is a social loss. If $\bar{b}$ is sufficiently high, the only equilibrium entails waiting time, since the players will choose slot s_1 . A more efficient situation is obtained when a toll, equal to $\bar{b}$, is imposed on the user who crosses during slot s_1 . Under the new equilibrium both players will be indifferent between the two slots and the configuration where each player chooses a distinct slot becomes an equilibrium. This is how the time-varying toll described above works for a continuum of players.

It is important to notice that the dynamic toll does not reduce the number of trips. Instead, it motivates the drivers to adjust their departure times. This observation is similar to the remark we have stated for the static case when we move from the single route to the case of a network where each pair of origin and destination is linked by several routes: the number of trips does not decrease but traffic is diverted to less congested routes. Most realistic situations correspond to a dynamic framework with several possible routes for each trip. In that case, the effectiveness of the first-best congestion toll will indeed depend on the flexibility of the drivers in various dimensions, especially the spatial and temporal ones.

Further Issues and Conclusion

This overview of first-best congestion pricing has not addressed all issues and possible extensions, but has deliberately focused on fundamental features of road pricing. The case of heterogeneous users has been shortly mentioned above when we discussed road pricing in a complex networks. Users have distinct origin-destination pairs and are not, by so, homogeneous. More generally, it is also possible that users have distinct desired arrival times, distinct trip purposes or may use distinct vehicles as in [de Palma et al. \(2008\)](#). In most cases, taking into account these extensions will involve a more elaborated analytical models but there are no insuperable difficulties. The essence of first-best pricing, that we have encountered along all the examined situations, is that each user should pay the external costs he generates during his trip. This is the basic ingredient for an efficient allocation of roads.

The correct value of the first-best congestion toll, depends on data related to users and the spatial and temporal patterns of the trip, among other details. In practice, this data is not easy to obtain and one may consider an approximate value of the first-best toll as in [Kilani et al. \(2014\)](#). In the dynamic case, instead of a smooth time-varying toll it is possible to consider an approximation through a step function with flat toll on given time intervals. Implementing a toll for off-peak period and peak period is the simplest approximation. As the number of intervals increases, with optimized toll levels within each interval, the social loss is reduced and at the limit we converge to the first-best situation. [de Palma et al. \(2005\)](#) show that fine tuned tolls provide a substantial benefit by comparison to flat tolls.

Some years ago the computation of the exact value of the first-best congestion toll was simply impossible, because it requires perfect information on all the trips. But, this situation is changing. Indeed, with the growing technological innovations in the geolocation and connectivity of cars, the autonomous car, it is easy to trace back the exact route, the departure time and the arrival time for any trip. The implementation of first-best congestion toll will no longer be limited by scarcity of data, but mainly by the acceptability of users and the goodwill of decision makers.

As a final comment recall that in the bottleneck problem, there are no external costs under the optimum (no delays). This is not a universal characteristic of the optimum, however. Indeed, as shown in the case of one road link and a continuum of users (**Fig. 1**), some congestion is prevalent in the optimum. The absence of congestion in the bottleneck is mainly the result of the assumption that external cost is only in the waiting queue and not on the road.

Introduction

Cost-benefit analysis (CBA) accounts for all benefits and costs of a project, measuring every item in monetary terms. It is often the case that consequences of the project are non-market goods and, therefore, there is no price to insert in the analysis (i.e., saved time, lives, landscape, and environmental goods, which would be the main non-market goods relevant for transport appraisal). To account for a social value of these concepts it is necessary to find a link between these goods and existing market goods. Economists have developed methods to obtain these estimations applying Revealed Preferences (RP) and Stated Preference (SP) questionnaires such as Choice Experiments (CE) and Contingent Valuation (CV).

People might feel uneasy with the idea that life, environment, and time can have a value. In general, there is a tendency to reject any valuation of non-market goods, in particular the value of statistical life (VSL) and the value of the environment. The first problem arises with the mere institution of price. Bringing those concepts to the market arena seems to challenge our moral concerns because they do not seem legitimate objects with which to trade. This view is widely popular, and reflects a profound dissociation between economic analysis and society's perspective. If we are using these techniques to come up with a social value how is possible that most people reject it?

For instance, in relation to the VSL the Indian Environmental Minister Kamal Nath in 1993 stated:

"... the absurd and discriminatory Global Cost/Benefit Analysis (. . .) we unequivocally reject the theory that the monetary value of people's lives around the world is different because the value imputed should be proportional to the disparate income levels of potential victims . . . it is impossible for us to accept that which is not ethically justifiable, technically accurate or politically conducive to the interests of poor people as well as the global common good" (Grubb et al., 1999, p. 306).

In relation to environmental goods people tend to think that wildlife, biodiversity, and landscape are priceless or, at least, difficult to measure in monetary terms. It is often the case that nature is contemplated from the perspective of rights, non-related to the enjoyment and services that nature produces to human beings. This makes it more difficult to accept the idea of value. As Elton (1958), states: "There are some millions of people in the world who think that animals have a right to exist and be left alone, or at any rate that they should not be persecuted or made extinct as species. Some people will believe this even when it is quite dangerous to themselves. p. 143–45."

These and other examples demonstrate that ethical objections to monetary valuation of non-market goods are widespread. In this chapter, we will provide an answer to these concerns following this structure: first, we describe the neoclassical approach and its difficulties; second we explain why monetary value is ethically acceptable; and close with a section of conclusions.

The Neoclassical Approach and its Ethical Problems

Underlying any CBA is neoclassical economic theory, which is rooted in utilitarianism. The basic assumptions might be formulated as: individuals maximize their utility, which is obtained from a bundle of goods. The key aspect of the theory is the flexibility of the utility function, which includes all type of goods not only market goods but also environment, safety, exposure to air pollution, and any other non-market goods. At the same time, individuals are constrained by budget and time. Giving these limitations, in order to

maximize their overall utility individuals are willing to make trade-offs between different goods. This opens the space for extracting willingness to pay, which is the marginal rate of substitution between income and any other good. Hence, we are assuming that individuals are willing to trade between goods according to their preferences and constraints.

In practical terms, economists observe secondary markets that keep a substitution or complementary relation with the non-market goods. For instance, VSL could be estimated by observing wage differences for jobs that have different levels of risk of a fatal event, *ceteris paribus*. Environmental goods could be estimated by accounting for all costs incurred to visit a National Park; air pollution can be valued through house price differences and the cost of moving from polluted to non-polluted areas; or from the price of goods that prevent its consequences such as masks and air purifiers. By the same token, the value of time is indirectly observed by comparing choices of different modes of transport that comprises a trade-off between time and money. All of these are RP methods that might be combined with SP.

Although environment, life, and time are obtained based on the same principles, their ethical consequences are not exactly the same. We will present them separately

Environmental Goods

In CV experiments, it has been observed that a fraction of individuals provide protest responses. These answers could be zero bids, or infinite bids, or simply a refusal to offer any monetary value. Although protest responses would have different motivations, one possible interpretation is that these individuals are reluctant to accept any exchange value for these non-market goods. Indeed, when non-traders are asked the reason of their zero bids, often the answer is “I refuse to assess biodiversity (or any other environmental good) in monetary terms.”

Economists offer another explanation for non-traders: they might show lexicographic preferences. If people have lexicographic preferences for environment, they refuse to trade between environmental goods and market goods, because the preference for environmental goods is absolute. No matter what is the gain in terms of other market goods, they would always select the bundle with the higher level of environmental goods. These preferences cannot be represented with a utility function. It might be also the case of weak lexicographic preferences where trade is possible but only beyond certain threshold (for instance, certain level of income).

Yet it might be the case that individuals reject any compensatory rule between environmental goods and the rest of the goods in the bundle, simply because they consider that environment has *rights* and, hence, should be protected regardless of the cost or benefits for the society. In this line environmentalists usually allege that non-market valuation techniques are anthropocentric, that is, based on utility (of individuals) disregarding nature as an object that generates certain services.

For some individuals environment cannot be categorized as a good and therefore, exchange with other goods is not possible. It is simply that not all goods are exchangeable. As Throsby wrote:

“First, I may acknowledge that a good has value to me, but I cannot trade this benefit for other goods – in other words, I cannot meaningfully represent the benefit I gain from this good in monetary terms. For example, I may experience some pleasure at my sense of identity as a human being (sharing a common humanity with my fellow citizens), but neither I nor they are likely to be able to express the value of this identity in monetary terms, since it is not exchangeable for other goods” (Throsby, 2003, p. 278).

The Value of Statistical Life

The VSL is usually obtained from three sources: wage differences in riskier jobs; market for goods that increase safety (smoke detectors, safety features in a vehicle); and SP surveys that comprises the risk of a fatal event related to risky behavior (diet, smoking, pollution). Initially we should face the same problems that arise with environment: that is, the idea of using money to value life seems morally repulsive. However, if we actually understand that it is not the value of a life but the willingness to pay to prevent a fatality, this rejection might not be justified.

This does not mean that there are not many ethical issues around the concept of VSL. Firstly, the VSL depends on market conditions: this value changes with recessions, market conditions, and consumer preferences. Most of the VSL estimates come from analysis of fatalities in the labor market. As a result, estimations of VSL tend to increase with time partly because workers are more aware of the risk in their working conditions.

Secondly, since VSL is a budget limited estimation it is expected to be lower in developing countries; that is, life is less valuable in poorer countries and for poorer people. An early paper from Miller (2000) demonstrated the existence of a correlation between GDP per capita and the VSL where VSL can be approximately 120 times GDP per capita. This wide range of values suggests that the most efficient allocation of resources is to pollute in developing countries since there life has less value. As Miller points in his article: “In 1991, World Bank Vice President Lawrence Summers suggested that it might be economically efficient to transfer pollution to less developed countries where the productivity losses of ill health would be smaller” (p. 16).

Most people would agree that life should have a value per se, no matter who and where. Yet the implications of this idea are ethically unacceptable. Do we have to spend the same resources to save the life of a child versus the life of an elderly person? In transport projects, VSL is usually applied per person regardless of age and other conditions. In contrast, health care policy typically uses the quality of adjusted life year (QALY), which recognizes that the value of life decreases with age.

The Value of Time

Travel time savings is usually the most important benefit generated from any transport project. The ethical implications are, somehow different. We do not see here people opposed to the idea of measuring time with money since everybody does it –what is working after all?. However, estimations of the value of time (VT) could be *regressive* in the sense that they benefit to a minority of the population that are usually the richer. The idea is straightforward: since the VT comes from revealed and stated preferences, these are budget-limited, and higher VT will arise for those who have more money. Indeed, five decades of investigation of the VT, shows a higher WTP for faster modes of transport that are correlated with income. The greater the income, the faster the mode, the higher the VT. Hence, decisions about transport projects might end up benefiting the most advantaged group of the society. For example, lower income groups are often users of buses who have a lower WTP to save time. Hence, public investment might accrue to the development of highways and roads rather than more buses. To overcome this problem a so-called “ethical value of time,” based on average income level, has been introduced.

Utilitarianism Versus Deontological Ethic

Utilitarianism is a philosophical school founded by the English philosopher Jeremy Bentham in the 18th century. This doctrine considers the rightness of any act as dependent on its consequences—that is why it is also called consequentialism or Conditional Imperative: consequences are the only thing that matter. Thus, an action that increases the happiness of individuals is right, and vice versa. This is the origin of utility analysis and its maximization as the basis of any welfare assessment. This is also the idea behind CBA, which considers all costs and benefits of a project, that is, its *consequences*, to determine if it is good or bad, and whether the project should to go ahead or not.

In contrast, Deontology is a rule-based ethics: Any course of action is right if it is according to a *general principle of ethics*. We have to do what is right regardless of its consequences. What is “right”? What are the “rules”? It could be the Ten Commandments, but following Kant we can use his Categorical Imperative. One of its most well known tenets is this: act in a way that everybody is a goal and not a means. The corollary of this rule is that everybody counts and everybody matters equally. More or less life cannot be exchange for any other good since this would be using life as a means. Likewise for environmental goods. The whole idea of CBA would be absolutely rejected. The typical example to understand these two different doctrines is this: a terrorist has placed a bomb in a school. Torturing him and obtaining information to save the children is acceptable according to Utilitarianism; but the deontological ethic would rule against this because torture is immoral, no matter the consequences.

Intrinsic or Absolute Value Versus Economic Value

Parallel to this discussion of ethics principles is the idea of value: economic versus *intrinsic value*. Economic value stems from utility, using stated or revealed preferences. Intrinsic value is the value per se of environment or life (let us exclude time here). Environmentalists would consider that wildlife is not an instrument for human enjoyment but an end itself. In this sense, wildlife would have an intrinsic value. Another perspective is considering that an object has an intrinsic value through the properties that the good possesses: objective and not subjective measurement.

Intrinsic value comes from deontological ethics. That is, environmental goods cannot be used as exchange for something else (money) since this would mean that these good are treated as means and not goals. In this sense, any economic value would be unacceptable. Hence, the discussion could be about *intrinsic* versus *economic* (or instrumental) value.^a Which one should guide our actions as a society? Which one is ethically acceptable?

As mentioned before environmentalists consider that nature has an intrinsic value, that is, a value that is independent from any human. Even if we accept that this is the case—and precisely because this is the case, that is, a value, which is independent to human affairs—there is no reason to think that this intrinsic value brings any obligation to human beings. As O’neill (2002) states: “The defender of nature’s intrinsic value still needs to show that such value contributes to the well-being of human agents.”

Likewise, a permanent appeal to intrinsic value does not yield practical results. Again, it leaves the society without appraisal tools for any project. Indeed, during recent decades, this recurrent moral argument about the intrinsic value of nature has been unable to stop the degradation of ecosystems. In contrast, instrumental or economic value has been used to apply practical tools that have curbed, at least partially, the environmental catastrophe.

VSL, Healthcare and Scarce Resources: A Standard is Essential

Following the intrinsic value argument, we would reach the conclusion that life is ethically incommensurable and its value, if exists, would be the same for everybody. In contrast the VSL is based, mostly, on individuals’ WTP to prevent a fatality. But, what would be the result if we consider the lives of other people? Recently an article was published in *Nature* about finding rules for self-driving (Awad et al., 2018) where participants are forced to choose which life to spare in case of a hypothetical accident. It is the largest survey

^a In Kant words: “Everything has either a price or a dignity. Whatever has a price can be replaced by something else as its equivalent; on the other hand, whatever is above all price, and therefore admits of no equivalent, has a dignity. But that which constitutes the condition under which alone something can be an end in itself does not have mere relative worth, that is, price, but an intrinsic worth, that is, a dignity.”

of ethical concerns ever taken with 2.3 million people around the world. Using 13 scenarios in which someone's death was unavoidable the results shows a ranking where age, gender, and even responsibility matters.

This article reflects people's mindset about the life of others, and its results clash with the basic ethic idea, present in many constitutions, that nobody should be discriminated against based on features such as age, gender, and so on. This outcome is contrary to the Kantian ethics notion that all life matters the same, and hence no discrimination is possible. In short, this research points that, sometimes, choices are unavoidable which makes it impossible to apply intrinsic values for life.

Another way to contemplate the morality of the VSL is to recognize the contrast between the growing demand for healthcare services and the permanent scarcity in the supply. The logical outcome is searching for efficient treatments and this implies that we need *standards* to come up with the right choices. Standards such as the VSL, or QALYs. The lack of such measurements would make impossible to make choices in healthcare. In real life choices are made constantly, revealing that this is how people actually think. As Calabresi (1965) pointed

"Our society is not committed to preserving life at any cost. In its broadest sense, this rather unpleasant notion should be obvious. Wars are fought. . . . But what is more interesting . . . is that lives are used up when the quid pro quo is not some great moral principle but 'convenience.' Ventures are undertaken that, statistically at least, are certain to cost lives. . . . We take planes and cars rather than safer, slower means of travel. And perhaps most telling, we use relatively safe equipment rather than the safest imaginable because –and it is not a bad reason – the safest costs too much."

In addition, we should add that the VSL is meant to create a standard that saves lives. It does not imply benefits arising from projects that kill lives. That is why the "value of a preventable fatality" (VPF) has been proposed as a more appropriate name.

Altruism and Environmental Goods

In relation to environment and, following utilitarianism, it is possible to create a framework of different values (Krutilla, 1967). First, *use-value* is that which individuals obtain from using environmental goods, even if it is a potential use. Aside from use-value, WTP for environmental goods might reflect individuals' ethical values, beliefs, and attitudes. This would affect the so-called *non-use or passive value*. When individuals behave altruistically, they incorporate the utility of others into their decisions. Their WTP for environmental protection will reflect their desire that future generations, or others, in general enjoy environmental goods. In this respect, there is a distinction between *non-paternalistic altruism* where individuals are willing to pay for any public good that reflects public preferences, and *paternalistic altruism* where this would only happen for certain goods that reflect the payer's preferences (for instance, environmental goods). There is evidence of existence value in the support of environmental NGOs and altruistic donations, aside from thousands of stated preference experiments.

Paternalistic altruism, also known as warm-glow represents for Kahneman and Knetsch (1992) the "purchase of moral satisfaction." Likewise individuals might obtain satisfaction from an environmental good not because of altruism, but because of the knowledge that this good exists—without obtaining any services from it. Simply knowing it exists makes them feel better. This is an *existence value*. The fundamental reason for this is sentimental: As expressed by De Groot et al. (2002): "Natural ecosystems and natural elements (such as ancient waterfalls or old trees) provide a sense of continuity and understanding of our place in the universe which is expressed through ethical and heritage-values. Also religious values placed on nature (e.g., worship of holy forests, trees, or animals) fall under this function-category."

This might not convince environmentalists, who care about environment not for the services that this good provides to him/herself or to others, but because of nature *itself*, understanding nature as a subject with rights. In this case, since it is a value that arises from a non-human perspective, it can be considered an *intrinsic* value.

Nonetheless, in all these cases individuals still behave in a selfish manner in the sense that, after all, they are maximizing their utility. A step further would be *genuine altruism* where the enjoyment of others does not bring any increase on the payer's utility (Sen, 1977). Table 1 summarizes this framework of values.

Coming back to the discussion of intrinsic versus economic value there is a possible compromise here since some individuals' interpretation of existence value might reflect an intrinsic value vision. Under some flexible interpretation—a non-anthropocentric value—this could be accepted as intrinsic since nature is not used as a means but as a goal. We should expect that, at least partially, stated preferences values reflect this vision. In fact, the Millennium Ecosystem Assessment states that "many people do believe that ecosystems have intrinsic value. To the extent that they do, this would be partially reflected in the existence value they place on that ecosystem, and so would be included in an assessment of its total economic value" (Millennium Ecosystem Assessment, 2003, p. 133–134).

Table 1 Environmental non-use values

Variation in individuals utility (payer)	Beneficiary	Preferences	Motivation	Name
Positive	Others	Others	Public goods	Pure altruism
Positive	Others	Payer	Purchase of moral satisfaction	Paternalistic altruism
Positive	None	Payer	Self-transcendence	Existence value
Positive	Nature	Payer	Environmentalism	Intrinsic value
Null	Others	Payer	Commitment	

Conclusion

An intrinsic value for environment might exist and, perhaps, co-exist with exchange value, but it must not undermine the use of economic value to organize social preferences. Intrinsic value arises from environment per se and, since it is a non-anthropocentric perspective, it cannot bring any obligation to human beings. Besides, the use of intrinsic value does not yield any solution for the environmental catastrophe. It is like asking for zero pollution, which is not a feasible option. The use of economic value in the environment provides a useful framework to make choices. Using intrinsic value instead would be impractical to manage.

However, deontological ethics might play a role since individuals would consider their beliefs in their WTP and hence, at least, partially it might be possible that their WTP reflects an intrinsic value for environment. The current practice of CBA and cost-effectiveness in healthcare brings a reasonable compromise with deontological ethics—counting VSL regardless of the characteristics of the person in transport projects, and applying QALY—, which considers age and life expectancy- for healthcare treatments.

Having said that, it is true that not everything can be valued in monetary terms as Throsby argues, but we need standards to make the right choice, to allocate scarce resources, and, in this sense, Utilitarianism is essential. The resource allocation argument is “just,” because the alternative is a dead end. It is unethical not to consider values (costs and benefits), because failure to do so is to ignore alternatives, which might improve the welfare of society.

As human beings, our actions constantly support the exchange argument. In relation to the value of life for instance, zero risk does not exist. Similarly, nobody can realistically ask for zero pollution, or face all the costs and sacrifices necessary to achieve such an outcome. We make trade-offs constantly, increasing or decreasing our risks and revealing our willingness to pay. Using an absolute value would bring to the world an ethically unacceptable tenet, where we would be unable to make choices between healthcare treatments.

In relation to the value of time, most objections are about the regressive calculations that are biased toward population segments with higher WTP. This is a valid concern and there are already possible solutions to mitigate this bias.

The opposition to non-market valuation reflects objections to market itself: to the use of money as a universal measurement, as a standard. The popularity of this position is rooted in a supposedly moral superiority of deontological ethics—we follow rules, we do not count-. Yet this position is impractical, and it is refuted every day with our own behavior as choice-makers, always trading, comparing and exchanging private goods for non-market goods.

Introduction

Transport systems in many countries are heavily congested, particularly in urbanized areas and during peak hours. Congestion leads to longer, less predictable travel times and has been shown to have a large social cost. The monetized cost of time lost due to congestion in the US has been estimated at 0.9% of the country's GDP (Schrang et al., 2012). Including the value of wasted fuel raises this number to 1.7% of GDP. On top of this, one should consider the social cost from human exposure to the air pollutants generated by the combustion of fuel due to congestion. The latter accounts for 2.9 billion gallons of fuel annually. Taking the health cost of traffic-induced air pollution into account implies social costs that may well exceed 2% of GDP. Standard economic analysis argues that, in the absence of policy interventions, the level of traffic exceeds the socially desirable level. This happens because road users base their trip decisions exclusively on their own travel times and costs. They do not account for the effect of their decisions (where, how, and when to travel) on the travel times and costs of the other road users; that is, they disregard the external cost of road use.

The external cost of road use can be very high during the peak hours, due to the large number of vehicles affected by changes in travel times and travel time reliability, and because congestion effects are worse the more dense traffic is. This suggests that reducing peak hour congestion can result in large welfare gains, at least if that is done in a way that selectively eliminates trips whose social costs exceed their social benefits.

Road tolls that vary across time and space are the best way to reduce congestion, because they allow for a wide array of behavioral changes: change of the time at which a trip is undertaken, change of route, switch from private vehicles to public transport, change of residential or workplace location—or pay tolls and continue to drive under reduced congestion. In the long run, urban road pricing may contribute to creating more compact, less car-dependent urban forms. In contrast, traffic regulations, such as partial traffic bans, risk eliminating trips with a relatively low social cost. For instance, an odd–even system of car bans was introduced during 1990s in Athens, allowing vehicles whose license plate ends in an odd (even) number to enter a specific area in odd (even) days. Variations on this type of measure, which is not relevant to the social cost of the trip, have been implemented in Latin American, Chinese, and European cities.

The standard case for congestion charging abstracts from road users' trip purpose. It treats the demand for peak hour driving as a derived demand, and the willingness to pay for trips as a measure of their full social value. As a result, there is no need to account for the precise reasons people travel. However, a considerable portion of peak hour travel is undertaken to commute to or from work. For instance, in Auckland (New Zealand) commuting kilometers make up approximately 46% of the total distance traversed by motorised vehicles during the peak hours. A tax on peak hour driving could result in an increase of the effective tax rate on labor income. What does this mean for the net welfare impact of urban road pricing, if labor markets are subject to large tax-induced distortions? How strong is the interaction between the inefficiency related to congestion during peak hours and the inefficiencies resulting from high labor taxes? What are the implications for urban road pricing policies *per se*? What are the recommendations on how to deploy the revenues from congestion charges?

This article draws from economic analysis of the past two decades to discuss if and how interactions between labor markets and congestion alter the overall case for congestion charging. It starts, in Section 2, by introducing two polar cases: one in which congestion charges are economically indistinguishable from labor taxes and one in which the bases of the two taxes do not overlap. Section 3 considers intermediate cases. Section 4 weighs the evidence, asking what practical rules of thumb are best for the design of congestion charges.

¹Views and opinions expressed in this article are the authors and not necessarily those of the OECD. We would like to thank Ian Parry for comments on an earlier version. The usual disclaimer applies

Figure 1 Schematic depiction of the interaction between a labor income tax and a road toll. Left panel: the polar case in which the bases of the labor and road tax overlap completely; middle panel: the intermediate case, in which the two taxes interact partially; right panel: the standard polar case in which interactions between labor taxes and road charges are not considered.

Two Polar Cases

The Standard Case: Labor Supply is Independent of Road Pricing

The standard case refers to a setting in which the road and the labor tax do not interact. In that case, the two tax bases are disconnected, as illustrated in the right panel of Fig. 1. Economic efficiency requires taxing road use at its marginal external cost, since all relevant sources of economic inefficiency, such as taxes and price regulations, have been assumed away. A lump sum recycling of revenue is economically efficient, since all taxes that could interact with the road tax are at their optimal values, essentially zero. This is the case because there is no predetermined level of revenue to be raised. The standard case is depicted in Fig. 2.

The Alternative Case: Strict Complementary Between Peak Hour Car Travel and Labor Supply

Suppose that all morning peak hour travel is for commuting, and the evening peak consists exclusively of trips back home from work. All workers drive a car, so there is no public transport or carpooling. Furthermore, the starting time of the workday is fixed, so workers cannot avoid congestion or charges by adjusting departure time. Also, the length of the workday is fixed. Changes in labor supply can take place through working more or fewer days, but not through working more or fewer hours per day. All workers are homogenous in skills and earn the equilibrium wage in a competitive labor market.

In this setting, all traffic results exclusively from commuting, and commuting is strictly proportional to labor supply. We illustrate this in Fig. 3, in which every unit of labor supply (lower panel) corresponds to a unit of traffic (upper panel). As a result, the base of the labor tax is identical to that of the road toll (Fig. 1, left panel). The two taxes—labor tax and road toll—differ only in name, as

Figure 2 Efficiency-maximizing road externality taxation in absence of other relevant inefficiencies. Shaded triangular area: deadweight loss due to traffic-related externalities; Shaded rectangular area: the total revenue from road pricing; height of rectangle: the level of the efficiency-maximizing toll; thin vertical line: overall traffic level without intervention; thick vertical line: efficiency-maximizing level of traffic.

Figure 3 Road externality taxation under the perfect complementarity polar case. Upper panel: transport market, as explained in Fig. 2; Lower panel: labor market; thin vertical line: the equilibrium traffic and labor supply with a labor tax of 40%; thick vertical line: the equilibrium traffic and labor supply with a labor tax of 40% and a toll equal to the marginal external cost of road use; triangular shaded area (upper panel): gains from marginal external cost pricing on the road; trapezoid shaded area (lower panel): labor market losses from marginal external cost pricing; dashed vertical line: the efficiency-maximizing level of traffic, achieved with a negative toll on the road.

their economic effects are identical. Both affect the same behavioral margin, namely the decision on how many workdays to supply. Consequently, the sum of the road toll and the labor tax determines the size of market distortions, but the separate components do not matter. That is, increasing the road toll has no economic effect if the labor tax is reduced by the same amount.

In this case, the road toll reduces welfare if the labor tax exceeds the marginal external cost of road use, unless the labor tax is reduced to compensate for the road toll. We illustrate that negative outcome of introducing marginal external cost pricing on top of a rigid labor tax in Fig. 3. The tax generates considerable gains on the road, but these are offset by the losses in the labor market. In fact, in this polar example the efficiency-maximizing level of traffic lies above that of the no-toll case. That level can be reached only with a negative toll, which functions as an indirect way to reduce the burden in the labor market.

Labor taxes are high in many countries and likely exceed the marginal external congestion cost associated with typical commuting patterns. For instance, assuming a kilometeric external cost of €0.30 and an average commuting distance of 30 km (both ways) implies a daily external cost of €9.00. The average gross income in the OECD was approximately €45,000. Using an average annual labor supply of 1744 hours/year and assuming a working day of seven hours implies approximately 250 working days a year. In turn, this implies an average gross daily wage of €180. Multiplying that by 0.255, i.e. the average labor income tax rate in the OECD, yields a daily labor income tax of €45.9, which is more than five times larger than the generated external effect of commuting. For this reason, the result from the polar case is sometimes taken as a warning against the introduction of urban road pricing, when the latter is not combined with cuts in labor taxes. The concern is that alleviating traffic externalities may inadvertently result in larger labor market distortions that could offset the welfare benefits from abating these externalities. Combining road charges with labor tax cuts avoids these adverse effects. To what extent should that warning be taken into account in practical efforts to curb urban traffic externalities?

Weakening Strict Complementarity Between Labor Supply and Commuting

Relaxing the strong assumptions of the polar case leads to weaker interaction between the labor tax and road toll bases and reaffirms the case for road tolls.

Two Commuting Modes

Suppose that, in addition to commuting by car, workers can opt for public transport (Parry and Bento, 2002). For simplicity, public transport is not subject to economies of scale and there are no external costs associated with it, so the marginal social cost of its provision is constant. In contrast to the polar case, there is now a difference between the tax on labor income and the congestion charge. The labor tax is the same for those commuting by car or by public transport, but the congestion charge applies to car commuting only.

How should the congestion charge be set in this context? To maximize efficiency, the policy maker prices public transport at its resource cost and introduces a congestion charge on the road. With the labor tax present, and without any “sophisticated” form of revenue recycling, *i.e.* any recycling mechanism other than lump-sum transfers, the optimal road tax lies below the marginal external cost of road use. The difference depends on the degree to which public transport can substitute the use of car. In the extreme case in which substitution is perfect, road traffic is taxed optimally at its marginal external cost.

Two Trip Purposes

The polar case considers commuting transport only. How do insights change if, instead, account is taken of the fact that there are diverse trip purposes? Key observations can be deduced from a stylized setting where commuting traffic coexists with “leisure traffic” (Van Dender, 2003). The latter encompasses all non-commuting trips and is a relative complement to leisure, while the former is strictly complementary to labor supply. In this case, the tax base of the labor tax and the road toll differ. The labor tax applies to days worked only, whereas the road charge in addition applies to the non-work activities from which the demand for leisure transport is derived.

Consider first the case in which it is not possible to reduce the labor tax and the road tax cannot be differentiated between the two user types. To maximize efficiency, policy makers should set the uniform charge to a level that equates two welfare components: (1) the gains from a reduction of road externalities induced by a marginal increase of the road tax and (2) the losses in the labor market, induced by the same adjustment. If there is only non-commuting traffic, the optimal tax is the marginal external cost of road use. In the opposite case, the optimal tax is zero. Empirical observation suggests that 35%–70% of the kilometers generated within the peak hours are not related to commuting. This indicates that road pricing during commuting hours remains relevant, even in the presence of strong tax interaction effects.

Suppose next that commuters can be distinguished from the rest of the road users. Since non-working trips are relative complements to leisure, introducing a differentiated charge allows to shift the burden of the road tax from (relatively heavily taxed) labor to (less taxed) leisure, with the potential efficiency gains as described in standard optimal taxation models. This implies that efficient charges on leisure trips may lie above marginal external costs, while commuting trips are charged at a fraction of it. Differentiating charges between trip purposes is hard to do directly, as the latter are not directly observable. However, *ex post* deductibility of the road tax paid for commuting trips from income taxes may allow for reasonable approximations.

To summarize, charging marginal external costs to non-work travel is, in many cases, justified. Higher charges can also be considered if revenues are used to cut labor taxes. Optimal surcharges are hard to quantify, so sticking to the simple rule is a sensible pragmatic option. The downward pressure of road charges on real wages can be mitigated by making the costs tax-deductible, in addition to ensuring that revenues are used to keep labor taxes as low as possible.

Weaker Links Between Commuting and Labor Supply

The strict complementarity case stipulates that each workday is of fixed length and requires a commuting roundtrip. There are various reasons why there can be more flexibility in the relation between labor supply and commuting. For example, even if the length of each worker’s workday is fixed, introducing time-varying road charges could shift the time of departure for the commuting and the home-returning trip. That is, a time-varying toll offers to drivers who are—in the polar case—subject to a strong tax interaction effect an option to commute in time intervals in which the toll is lower. This weakens the negative tax interaction effect, as illustrated in the intermediate case in Fig. 1. As a result, the efficiency of a road tax scheme can improve substantially by allowing time-varying tolls, even in the presence of a distorted labor market.

Another important departure from the polar case regards the possibility of adjusting the duration of the working day. In this case, part of the decrease in labor supply that the road toll induces can be offset through longer working days. The substitution effect will be larger the slower the rate at which the marginal productivity of an additional working hour diminishes during a working day, and the lower the value of leisure time is. If the marginal productivity of labor remains constant throughout the day and lies above the marginal valuation of leisure time, the two tax bases disconnect completely (Fig. 1, right panel). Then, the optimal road tax equals the marginal external cost of road use.

Figure 4 The interaction between a labor income tax and a road toll for different residential locations.

On top of the possibility that labor supply is elastic within a given day, teleworking constitutes another important margin that reduces the overlap between the two tax bases. If all professional groups have the possibility to work remotely with no impacts on wage or productivity, the remaining traffic is not related to commuting. Then, the optimal tax to that remaining traffic is the marginal external cost it generates (or even more, as part of a tax shift operation that we discussed above).

The upshot of these arguments is that, as flexibility to arrange working habits increases, road charges become more efficient and the tax interaction effect wanes (Fig. 2).

Spatial Considerations

So far, the discussion has abstracted from spatial heterogeneity, implicitly focusing on an average road charge across the road network. Such a charge converges to the overall marginal external cost of road use when the labor and the road tax bases are disconnected, while it approaches zero when the two bases overlap completely. What happens when the tax interaction effect is not constant across space, and the elasticity of labor supply varies with distance from the working location?

In this case, the spatial design of the charging system can be adjusted to target those segments of the labor force whose labor supply is less sensitive to changes in the commuting costs (Tikoudis et al., 2015; Tikoudis, 2020). That is possible as long as there is some distinguishable pattern of residential location, job location, or road use by these segments of the labor force. Such a spatially varying charging system may produce considerable welfare gains without a need to reduce the labor tax and even in the presence of a tax interaction effect that is, on average, substantial (Tikoudis et al., 2015).

To illustrate graphically this possibility, assume there are two households, one located close to the work location and one far away from it, as in Fig. 4. In the upper part of the figure, the tax interaction effect is weak far away from the employment hub but strong close to it. In that case, a cordon toll — which has the potential to charge particularly commuters from more remote locations — can be a more efficient option than marginal external cost pricing. The narrative is reversed in the lower panel, in which the tax interaction effect is lower closer to the employment location, possibly because that location is served well by public transport. In that case, it can make sense to leave the kilometers produced far away from the employment hub unpriced but to impose a charge close to the marginal external cost of road use near the city center. This requires that the scheme can identify (possibly using the home location of drivers) the long commuters and give them a free pass. In either case, the best results are obtained when tolls are low in road segments used by the parts of the labor force characterized by a strong tax interaction effect, and *vice versa*.

Discussion

Road pricing has the potential to improve the efficiency of transport systems by aligning the private cost of car use with its social costs. Relative scarcity of road capacity during commuting hours can result in high social costs, so the potential gains of better capacity use can be large. Road pricing can mitigate a series of traffic-related externalities more efficiently than traffic restriction schemes, as the latter risk eliminating trips whose social benefit outweighs their social cost. Mitigating congestion tends to reduce air pollution, resulting in significant additional benefits, particularly in monocentric areas with a dense urban core. During the peak

hours, air pollution in the central business district of these areas increases steeply due to car traffic, exposing a large portion of the population to high concentrations of air pollutants.

The potential welfare benefits of road pricing can be reduced by interactions with other tax instruments, such as the labor tax, whose base overlaps substantially with that of a road tax. In an extreme case, the interaction of the road and the labor tax is strong enough to render any road charge welfare-reducing, as the road tax increases the effective tax burden on labor. However, this polar case serves mainly as a conceptual device to illustrate how relaxing its underlying assumptions re-establishes the case for road charges that converge to the marginal external costs of road use.

The negative impact of road pricing on labor supply is much weaker when a substantial part of commuting trips can be rescheduled or can be undertaken by public transport. The same holds when longer days can give rise to fewer commuting trips. Also, flexibility in the length of the workday facilitates peak avoidance, and teleworking may be possible for some. For these reasons, the effect of urban road pricing on labor market inefficiencies is much weaker than what the polar case of strict complementarity suggests. If labor supply elasticity displays a clear spatial pattern, it is possible to design the charge system to tax higher the portion of traffic that is characterized by a lower elasticity of labor supply. Nevertheless, the risk that road pricing results in higher effective labor taxes when alternatives for car use are scarce and when worktime arrangements are rigid, is worth noting. In such cases, caution with high road charges is warranted.

The discussion also highlights how the economic benefits of urban road pricing depend on how the revenues from the charges are recycled to the economy. In the models discussed above, the labor tax distortion is often the main source of inefficiency in the economy. In that case, it is not surprising that using congestion charge revenues to cut labor taxes produces the most economically efficient results. Strict complementarity between labor supply and commuting implies that any other form of revenue use will possibly reduce welfare.

The more general message on revenue use is that cutting the most distortive taxes is preferable in an equal tax revenue yield analysis, and that it is crucial to ensure that road tax revenues are put to socially productive use. Socially productive spending options are many, but often include expanding public transport in urban regions. It was noted, above, that the availability of high quality public transport strengthens the case for congestion charging, as this helps keep commuting costs low. This suggests that using congestion charge revenues for improving public transport can make good economic sense. It also often makes good political sense, as public support for charging is easier when the revenues are recycled within the urban transport sector. In addition, combining urban area charges with urban area spending facilitates political ownership of congestion charges. The latter is more difficult to obtain when congestion charges are combined with labor tax cuts, given the different ministerial competencies that are typically involved in such an endeavor.

Introduction

The principle of aviation demand management at commercial airports involves using economic or administrative mechanisms, or a combination of the two, to reduce or redistribute air traffic at airports when airline demand for an airport service (usually expressed as a wish to land or take off at a particular time of day) outstrips the ability of an aspect of that airport's infrastructure to accommodate it. In most cases, the constraining factor is the available capacity of the operational runway/s. Airport demand management has the potential, if appropriately applied, to reduce flight delays and improve on-time performance (OTP), minimize airspace and airfield congestion, lessen local environmental impacts, and ensure high levels of safety and service at capacity-constrained airports. In short, airport demand management aims to control airline demand for airport access to address imbalances between airport capacity and demand. The following sections will introduce the concepts of airport capacity and demand management as they pertain to contemporary air transport operations.

Airport Capacity

A lack of airport capacity in major cities, particularly at peak times, is arguably, along with tackling climate change, one of the most challenging issues facing the global air transport industry. Many major airports can trace their origins to the 1940s or earlier when aircraft were smaller and lighter, air travel a mode of transport for the wealthy elite, and annual passenger numbers could be measured in the thousands. Today, primarily as a result of regulatory reform, enhanced competition, and technological innovation, the financial cost of flying has fallen in real terms and more than 4.6 billion passengers undertake airline flights every year, many commencing or ending their journeys at airports that have long since exceeded their intended design capacity. The economic and social implications of capacity constraints, which frequently manifest themselves in the form of flight delays, lost productivity, constrained connection possibilities, reduced competition, and passenger dissatisfaction are often cited as justifications for expansion. Indeed, when airline demand approaches or exceeds the ability of an airport to supply a safe and efficient service then congestion and delays invariably occur.

Capacity describes the ability of an aspect of an airport's physical or technological infrastructure (which includes, but is not limited to, runways, taxiways, terminal airspace, gates, ground access, security screening, border control, baggage handling, and other passenger processing activities) to safely accommodate demand. Demand in this instance is defined as the desire by commercial airlines to operate flights from an airport at a particular time of day and year. An airport's capacity is determined by complex interdependences between internal airport-specific and external political and environmental factors. Internal factors that influence airport capacity include: the number, siting, orientation, and physical characteristics of runways and taxiways (including their length, width, surface material, available lighting and navigation aids, and pavement strength); the size and layout of airside maneuvering areas and passenger terminal facilities; the configuration and limitations of proximate airspace; the presence of local site-specific environmental/noise curfews or other operating restrictions; and the nature of airline demand (particularly as it relates to flight timings, the size and mix of aircraft using the facility, the nationality of passengers, and each airline's business model). Airport capacity is also influenced by external factors, including local meteorological conditions, Air Traffic Control provision, Rescue and Fire Fighting cover, and national safety and security regulations.

Airport capacity is usually expressed in operational terms and describes the maximum number of air traffic movements (ATMs) that can be safely accommodated at an airport within a specific time period under specified operating conditions, service standards, and continuous demand. However, capacity is notoriously difficult to define and different countries (and even individual airports within one country) adopt different approaches and there is no universally accepted standard for measuring or defining it.

The two principal types of airport capacity are declared capacity and practical capacity. Declared capacity is an administrative tool that is used for strategic scheduling purposes and slot allocation. It typically specifies the maximum number of ATMs (defined as one

landing or one takeoff) that can be scheduled per unit of time. In order to ensure operational reliability and resilience, this figure can be quite conservative. Practical capacity, in contrast, is often a truer reflection of the number of movements that can be handled under ideal operating conditions and the figure is consequently higher. Irrespective of which metric is used, as demand approaches capacity delays generally start to occur.

The Airport Capacity Challenge

In the pre-deregulation and pre-liberalization era, airline regulation served as a form of capacity management and demand distribution. In the regulated era, national governments could dictate which airlines could fly, which airports could be served, the frequency and timings of services, the airfares that could be charged, and the passenger and cargo capacity of the aircraft that could be used on individual routes. Deregulation of the US domestic airline market in 1978 and subsequent moves toward deregulation and liberalization elsewhere in the world from the mid-1990s onwards fundamentally changed the nature of passenger and airline demand. Greater freedom of market entry and exit, seen as the characteristics of a contestable market, combined with low-interventionist free-market philosophies enabled new airlines to enter the marketplace where they established new routes and introduced a range of product and service innovations. Many of the new entrant airlines chose to compete on price, not service, and their “lower cost” approach to doing business (which only supplied what was necessary for safe and reliable flight) enabled them to pass on the savings to consumers in the form of lower fares. Cheaper fares stimulated unprecedented consumer demand for flying and passenger enplanements dramatically increased.

Incumbent full-service operators reacted to this new competitive landscape by consolidating their operations at key airports and increasing the frequency of services on their most lucrative routes. The formation of “fortress hubs” and hub and spoke networks improved connectivity and flight choice for their passengers and enabled the established airlines to protect their market share while minimizing costs and maximizing profit. However, the necessary scheduling of flights in “time banks” or “waves” to maximize connection possibilities led to peak-hour congestion and growing incidents of delay. The situation became particularly acute at major US airports, many of which were also often subject to the disruptive impacts of adverse weather conditions (including intense convective activity and thunderstorms in summer and snowstorms in winter). Growing delays led to economic disbenefits in terms of lost productivity, increased costs, a reduction in consumer welfare, growing levels of passenger dissatisfaction, and increased environmental externalities. One solution to the resulting demand-capacity mismatch was to expand capacity through the construction of additional infrastructure. However, this took time and required considerable capital expenditure. Another option was to modify existing procedures to enhance operational capacity or actively intervene in the market using administrative or economic instruments to manage demand.

Capacity Planning and Operational Enhancements

Capacity planning at airports is notoriously problematic. Air travel is a derived demand and one that is both highly cyclical in nature and vulnerable to external shocks, including oil price rises, geopolitical unrest, natural disasters such as volcanic eruptions, and global economic downturns. Airport development schemes that aim to increase capacity can involve anything from constructing or extending runways, terminals, and gates at existing facilities to building entirely new airports on greenfield sites and reclaimed land. Both options are very capital intensive and, in countries where extensive public consultation and/or public inquiries form part of the national planning process, may take decades to realize and become operational. In either case, airport development projects are furthermore often controversial owing to the required land take and the social and environmental impacts of airport construction and eventual operation on local communities and ecosystems.

The most important element in the airport capacity planning process is a forecast of demand over the life span of the planned infrastructure asset. In the case of terminal buildings, this can be 25–30 years or more. Forecasting demand for airport services that far into the future involves complex calculations seeks to anticipate changes in future passenger demand, predict disruptive changes that may occur to aircraft technology and energy sources, and foresee the continued evolution of airline business models. Future traffic forecasts are thus subject to significant uncertainties and the history of airport planning and development round the world is replete with examples of airports that have either been built to serve traffic that never materialized as predicted (such as Montreal’s Mirabel airport or Spain’s Ciudad Real facility south of Madrid) or airports which have been built to plans which failed to anticipate subsequent growth in demand. To mitigate this risk, many airports produce staged development plans that afford them the flexibility to incrementally adapt future airside and landside capacity according to low, medium, and high demand scenarios. In every case, the availability of finance is crucial, and the individual regulatory regime of each country worldwide will dictate the extent to which public or private (or a combination of public and private) finance is used to fund development activities.

In situations where the physical development of infrastructure is politically problematic or financially prohibitive, it may be possible for an airport to increase capacity through operational and procedural enhancements. These interventions typically seek to reduce uncertainties in the system and provide a more robust and resilient operational environment. Examples of operational enhancements include ground delay programs, airborne speed control, and better sequencing of arriving and departing flights. In Europe, the Airport Collaborative Decision-Making (A-CDM) program aims to improve OTP and enhance network reliability through improved communications between airport stakeholders while Enhanced Time-Based Separation (ETBS) air traffic control

procedures help to improve runway capacity at capacity-constrained airports during strong headwind conditions while maintaining safe separation.

Although such operational and procedural enhancements offer some potential for airports to incrementally improve capacity, if demand continues to outstrip capacity then some form of demand management intervention may be required.

Demand Management

Demand management can offer a relatively quick (though not necessarily ideal) solution to capacity constraints at a relatively low implementation cost. It also arguably makes for better utilization of a scarce resource. The demand management interventions that are appropriate for an airport are informed by a suite of models and analytical tools, of which three basic types can be identified:

1. Administrative

- a. *Traffic diversion*: A mechanism used to redistribute air traffic from capacity-constrained airports to proximate facilities with underutilized assets. This intervention will only work in a regulated market where the state is able to dictate which airports individual airlines can use to serve certain destinations. In a liberalized market, unrealized demand for airport access is often spilled to a neighboring facility with spare capacity. In this way, low-cost operators—who value operating from cheaper and less congested airports—have been able to grow traffic at previously underutilized regional and secondary facilities.
- b. *Traffic cap*: This intervention either stipulates the maximum number of scheduled ATMs or the maximum number of passengers who are permitted at a particular airport in any given time period. These caps are usually set by the national aviation regulator. In Australia, the *Sydney Airport Demand Management Act 1997*, for example, set a cap of 80 hourly ATMs. Traffic caps may also form part of the planning conditions for airport development. For example, a cap on the annual number of ATMs permitted at Heathrow was set at 480,000 as part of the planning condition for the development of Terminal 5. On the other side of London, in February 2018 the operator of Stansted airport applied to the UK's Civil Aviation Authority to raise the cap on annual passenger numbers from 35 to 43 m. In addition, some airports impose their own voluntary (and therefore nonenforceable) caps on particular types of movements for noise or other environmental reasons.
- c. *Slot control* or slot coordination: A slot (the permission to operate an aircraft at a particular time at capacity contained airports) is a *planning* tool for rationing and managing available capacity at airports where demand for air services exceeds the capacity of the airport's runway/s and terminal/s to accommodate it. Slot control or coordination is a quantity-based approach under which airports state their declared capacity and airlines request slots that are then allocated by an independent schedule coordinator. Administrative priority rules typically specify the order in which airline requests should be considered. Incumbent operators often benefit from "grandfather rights" on their existing slots, while any unused slots are returned to the allocation pool and made available for new entrant operators. Capacity-constrained European airports practice slot coordination, but this intervention is arguably both inefficient and anticompetitive as the allocation of slots is often based on historical precedent and the associated "use it or lose it" rules deny market entry to new operators while incentivizing operators to "babysit" slots and protect them for future years. The formal procedures used to coordinate global schedules at capacity-constrained airports are detailed within the IATA Worldwide Slot Guidelines. Currently more than 200 capacity-constrained airports around the world use slot allocation and slot control to manage demand in a way that is intended to be fair, neutral, and transparent. Nevertheless, allocating slots in this way is not without its critics and debates around slot reform continue.

2. Economic

- a. *Congestion pricing*: A price-based intervention that seeks to equate the price airlines pay for airport access with the marginal social cost (MSC) of capacity utilization. A number of airports charge differential fees depending on the time of day (peak/off-peak) and season that services are operated and some, who are operating in a competitive market, offer additional incentives in the form of fee reductions or waivers to attract airline services in off-peak periods. While airport charges are undoubtedly a factor in an airline's decision to operate from one location over another, as airport costs are only a proportion of an airline's total costs and the charging differentials are small, carriers can tend to be relatively price inelastic. Consequently, congestion pricing only has a minimal impact on airline scheduling behavior. The basic economics of congestion pricing is illustrated in **Fig. 1**. This figure illustrates the cost of delay on the vertical axis and the number of aircraft movements at a particular airport on the horizontal axis. The marginal private cost (MPC) represents the airline's private cost including the cost of fuel and the MSC curve includes the cost of flight delays. The cost of delays increases as the number of aircraft movements increases. Demand represents the demand for access to the runway and can also be seen as the marginal benefit. Without congestion pricing the number of movements is M1 and the airline operator's marginal internalized costs are C0. With this level of movement, however, the social cost exceeds the marginal benefit by AB and as such economists would suggest the introduction of a congestion price equal to CD, thus resulting in M2 movements, a social optimum. Up to aircraft movements of M3 there is no divergence between MPC and MSC essentially because the airline operators are not experiencing flight delays, with demand being well within the capacity of the airport. Historically, this has been a major component of the low-cost airline model with low-cost operators actively identifying secondary underutilized airports from which to operate their services. While congestion pricing can improve economic efficiency, it is not without its difficulties, not least in terms of

Figure 1 Delays and congestion pricing.

measuring the congestion costs and calculating the congestion price. The demand curve is also unstable, varying in relation to the peak and off-peak nature of derived demand, thus making it difficult to enact a differentiated congestion price. In addition, there is the issue of how the revenue generated from the congestion price (represented by $C1$, $C2$, and CD in **Fig. 1**) should be utilized.

- b. *Slot auctions*: Slot auctions represent another mechanism by which demand can be managed. Under this approach, airports specify a declared capacity and allocate the available slots to the highest-bidding airlines. This has the potential advantage that slots are allocated to the airlines that value them the most.

3. Hybrid

- a. *Market-based capacity allocation instruments*: These typically combine slot control and congestion pricing by allocating some slots and selling others. Secondary trading between airlines may be permitted to allow carriers to sell and purchase slots once the initial primary allocation has been completed. Hybrid mechanisms seek to enhance the efficiency of capacity allocation while addressing some of the practical challenges associated with economic interventions.

Irrespective of which approach is adopted, the aim of any demand management intervention is to reduce demand to a manageable level by modifying the temporal and/or spatial characteristics of airline demand to “de-peak” operations and/or redistribute flights to other airports.

Summary

Demand management can operate over varying timescales from the long-term strategic to the short-term tactical. Any form of demand management can deny some (potential) users free or complete access to the airport of their choice at the time of their choosing. The design of any demand management mechanism must be carefully considered and evaluated to ensure that it meets stated objectives to achieve the desired operational, managerial, and economic outcomes.

In contrast to capacity developments and operational or procedural enhancements that involve up-front investment costs but result in gains for all stakeholders, demand management imposes longer-term economic costs on airlines (in terms of scheduling options and route development) and consumers (in terms of airline choice and connectivity).

Any demand management mechanism involves a trade off between mitigating congestion and maximizing the utilization of available capacity. They must be robust and flexible enough to respond to changing operating conditions and continuous monitoring is required to improve airport demand management and capacity planning. Taken together, demand management and capacity planning attempt to address the demand-capacity mismatch that is evident at many of the world’s major airports.

Introduction

The great weight that the car has as a means of mobility in cities generates two significant externalities: congestion and pollution. Congestion produces traffic jams that affect commuter drivers, but also pedestrians that find their streets blocked by vehicles producing noise and pollution. Large cities around the world suffer typically from severe congestion problems. TomTom provides data about congestion levels in cities around the world using as indicator of congestion the additional time a vehicle needs to undertake a representative trip as compared to a free flow situation. On an average, most populated cities (with more than 1 million inhabitants) report congestion levels exceeding 20%. In peak periods, such percentage may reach values close to 100%. It must be stressed that the relationship between congestion and pollution is clear, since prolonged car circulation at reduced speeds has a notable effect on polluting emissions (Barth and Boriboonsomsin, 2008; Beaudoin et al., 2015; Parry et al., 2007).

The World Health Organization (WHO) has a database that measures air quality of the 3000 most populated cities in the world in terms of PM10 and PM2.5 (WHO, 2005). This type of pollution (mostly from urban traffic) is associated with increases in the mortality of the exposed population. According to the WHO, from an average annual concentration of 10 $\mu\text{g}/\text{m}^3$, there is an association between cardiopulmonary effects and mortality due to prolonged exposure to PM2.5 (this value is 20 $\mu\text{g}/\text{m}^3$ for PM10). The most severely congested cities in the world register serious pollution records far superior to the WHO guideline values. Indeed, these emissions are the main cause of the death of 3.3 million people per year in the world (more than AIDS, malaria, and the flu together).

In short, most of large cities around the world suffer the negative consequences of congestion and pollution associated to a car-based mobility. Hence, the implementation of policies to deal with such negative externalities is usually in the agenda of local governments.

Investments in capacity are extremely expensive, involve long gestation periods, and are ineffective in areas with dense road networks (Duranton and Turner, 2011). Therefore two types of measures can be applied depending on whether they are quantity or price-based. Low emission zones (LEZ) are the most popular quantity-based measures in Europe. The EU has shown a clear determination to reduce pollution, especially since the transposition of the directives 1999/30/EC and 2008/50/EC, which has been accompanied by the establishment of the “Euro” regulatory standards for vehicles. LEZ ban polluting vehicles from city centers. Thus their primary goal is not to mitigate congestion but to abate pollution. However, their effectiveness is logically conditioned by their impact on congestion. Around 220 cities in 14 European countries have implemented LEZ, including several cities in Germany, Sweden, Italy, or Greece, and cities such as London, Paris, Prague, or Lisbon. Examples of LEZ can also be found in large Asian cities such as Beijing, Tokyo, Shanghai, or Hong Kong. The precise way LEZ are put into service may vary considerably across cities, for instance, in terms of the intervention area or the type of vehicles being affected.

Price-based measures consist in charging congestion tolls, typically to enter/exit to/from the city center during peak hours. Tolls increase drivers’ travel cost and reduce traffic consequently. They have been applied in few cities, being the most important Singapore (1975), London (2003), Stockholm (2006), Milan (2008), Gothenburg (2013), and Palermo (2016).

In this chapter, we examine the effectiveness of congestion tolls and LEZ in dealing with congestion and pollution. The rest of this chapter is organized as follows. Section “A Simple Model to Explain the Effect of Low Emission Zones and Congestion Tolls” shows how urban congestion is modeled from a microeconomic viewpoint and the theoretical effects of congestion tolls and LEZ. Section “The Effect of Urban Tolls and LEZ on Congestion and Pollution” analyzes the results in the existing literature about the

effects of tolls and LEZ on congestion and pollution. Finally, Section “Conclusion: LEZ Versus Congestion Tolls” provides some final considerations.

A Simple Model to Explain the Effect of Low Emission Zones and Congestion Tolls

We first provide a welfare analysis explaining the inefficiency associated with congestion. Then we explain the effect of tolls and LEZ. Finally, we incorporate pollution into the analysis to provide an overall assessment by suggesting four scenarios depending on the effectiveness of tolls and LEZ.

The Excess Traffic Generated by Urban Congestion

Urban congestion is an externality that appears when traffic volume exceeds a certain threshold. The textbook model (Brueckner, 2011; Cantillo and Ortúzar, 2014; Lindsey and Verhoef, 2001) assumes that the time that a vehicle needs to undertake a representative trip (t) is a function of traffic (q), so that $t = f(q)$. The total time needed by all vehicles is therefore $qt = qf(q)$. Finally, the increase in total time that represents the introduction of a new vehicle is $\partial qt / \partial q = t + q \partial t / \partial q$ where the second term of the expression identifies the externality for the rest of drivers. We can define the congestion threshold $\tilde{q}$ so that, $\partial t / \partial q = 0$ for $q < \tilde{q}$ and $\partial t / \partial q > 0$ for $q > \tilde{q}$. Graphically, as shown in Fig. 1, the externality is the vertical distance between $t = f(q)$ and $\partial qt / \partial q$.

Reinterpreting t as the generalized travel cost, $t = f(q)$ and $\partial qt / \partial q$ can be understood as the average private cost and the marginal social cost associated to the trip and can be graphically represented as the private supply (S_p) and the social supply (S_s), respectively. If we incorporate a demand for travel (D), we obtain the equilibrium q^* , t_p^* represented in Fig. 2. Congestion increases the social cost

Figure 1 Congestion as a negative externality.

Figure 2 The equilibrium and the social optimum.

Figure 3 Quantity measures.

to t_s^* . The social optimum (q^{so} , t^{so}) is obtained from equaling the demand to the social supply and the difference $q^* - q^{so}$ indicates the excess traffic observed in equilibrium. The figure also shows the social welfare associated with car usage, which is positive (welfare gain) for $q < q^{so}$ (striped area), and negative (welfare loss) for $q > q^{so}$ (shaded area).

Measures: Congestion Tolls Versus LEZ

Two main types of measures can be applied depending on whether they are quantity or price-based.

Price measures: congestion tolls. A congestion toll increases the average private cost (t) up to the marginal social cost ($\partial qt / \partial q$). The optimal amount of the toll to recover the efficiency and eliminate the excess traffic equals the externality evaluated at the optimal number of trips $E = q^{so} \partial t / \partial q$. Such toll would internalize the externality while raising some additional revenue.

Quantity measures: LEZ. LEZ reduce the demand for travel. In case the contraction of demand would exactly eliminate the excess traffic, we would get the situation as shown in Fig. 3 where $q^* > q^{so}$.

Therefore, both congestion tolls and LEZ can be equally effective in eliminating the excess traffic if they are correctly designed. However, quantity measures generate welfare losses (new shaded area in Fig. 3) as they do not take into account drivers' valuations and are applied indiscriminately.

Extension of the Model to Incorporate Pollution

Consider now that there are two types of cars, new and old, so that the traffic volume is $q = q_{old} + q_{new}$ where $q_{old} = \lambda q$ and $q_{new} = (1 - \lambda)q$ with λ and $1 - \lambda$ being the shares of each car type. Supposing that new cars produce 0-emissions (i.e., electric cars), car pollution is given by $P = g(q_{old})$ with $g'(q_{old}) > 0$. Although both tolls and LEZ can eliminate the excess traffic generated by congestion, their effect on pollution is different with LEZ being in general more effective. The reason is that tolls do not discriminate between new and old cars, whereas LEZ only ban old cars. The relative effectiveness between both measures in mitigating pollution depends on the proportion of old cars λ , which tends to decrease over time as the fleet is renewed. In addition, as LEZ are announced some time before they are made effective, a certain accommodative behavior of local drivers can accelerate this car renewal process.

Overall Assessment of Congestion Tolls and LEZ

When assessing the performance of tolls and LEZ, we need to take into account their effect on both externalities. Looking at congestion (excess traffic), tolls are better because they are more efficient (as they take into account drivers' valuations) and at least equally effective, with the effectiveness of LEZ depending on the level of λ . Concerning pollution, the performance of LEZ is better, with the difference between the two depending again on λ . At this point, we can consider four scenarios.

- Scenario 1: $\lambda = 0$. There are no polluting cars and, therefore, LEZ produce no effects and are useless. Differently, congestion tolls can eliminate the excess traffic.
- Scenario 2: $\lambda \in (0, 1)$ low so that LEZ block every old car. In this case, LEZ cannot eliminate completely the excess traffic and are less effective than tolls in abating congestion but they are superior in mitigating pollution.
- Scenario 3: $\lambda \in (0, 1)$ high so that LEZ can eliminate the excess traffic by just banning old cars (assuming a contraction of demand that exactly eliminates the excess traffic). LEZ and tolls are equally effective in mitigating congestion and LEZ are superior in reducing pollution.
- Scenario 4: $\lambda = 1$. All cars are polluting, so that LEZ would ban all vehicle use.

The Effect of Urban Tolls and LEZ on Congestion and Pollution

Urban Tolls

From a theoretical point of view, there is a wide consensus among economists about the advantages of charging a price to get access to congested/polluted areas as a means to deal with the externalities related to car usage. However, the implementation of an optimal toll system is difficult, given that some essential decisions (such as the delimitation of the restricted area, the amount of the toll or the exempted vehicles) are inefficient as they are usually based on political considerations.

In addition, the empirical evaluation of the effects of price policies is a complex task. First, it is difficult to have an unaffected area comparable to the one affected by the toll system, as the restricted zone typically comprises a severely-congested city center. Second and most important, tolls are usually implemented along with improvements in the public transportation system. Therefore, disentangling the effect of two simultaneously applied policies that pursue the same final objective is problematic. Finally, another complication comes from the fact that drivers anticipate to some extent the effective implementation of tolls and accommodate their behavior in advance.

Taking into account these difficulties in identifying properly the effects of urban tolls, empirical evidence generally suggests that congestion pricing is an effective policy insofar as it tends to be associated with a sharp reduction in road traffic in restricted areas and, consequently, with a decrease in congestion and the emission of pollutants. The literature is composed by a series of papers that study the effect of urban tolls on individual cities by comparing traffic, congestion, and pollution levels before and after their implementation. Urban tolls are found to be effective in reducing congestion from the first year of implementation. The analyses for London and Stockholm show that urban tolls reduce congestion by 20%–30% (Börjesson et al., 2012, 2014; Eliasson, 2008; Santos and Fraser, 2006), while the impact is about 10%–15% in Milan and Gothenburg (Andersson and Nässén, 2016; Gibson and Carnovale, 2015; Percoco, 2013; Rotaris et al., 2010). In Singapore, the effectiveness of congestion pricing has been shown to be even higher as compared to European cities (Olszewski and Xie, 2005; Phang and Toh, 1997; Willoughby, 2000). Furthermore, some studies provide evidence on the effectiveness of tolls in mitigating pollution. The reduction in pollution lies between 6% and 17% in Milan (Gibson and Carnovale, 2015) and between 5% and 15% in Stockholm (Simeonova et al., 2018).

Additional positive effects associated with urban tolls have been also identified in the literature, for instance in terms of traffic accidents for London (Green et al., 2016) or in terms of children health for Stockholm (Simeonova et al., 2018).

The ultimate reason behind the underuse of urban congestion tolls has to do with their unpopularity. However, looking at the Swedish experience, this lack of social and political support seems to be a short-run effect (Börjesson et al., 2016; Eliasson, 2008). A recurrent argument against congestion charges is related with their supposedly regressive effects. Nevertheless, they are not necessarily regressive (Eliasson and Mattsson, 2006; Eliasson, 2016). In addition, funds obtained from the toll are typically used to improve public transportation and the mitigation of congestion reduces commuting times and, therefore, fuel consumption.

LEZ

While many studies have examined effects of congestion tolls, the empirical literature on LEZ is scarce and focuses on their effects on pollution. As mentioned above, studies on urban tolls usually focus on individual cities by comparing their performance through the analysis of traffic conditions before and after their implementation. Although some studies on the effectiveness of LEZ follow a similar methodology, other analyses compare pollution levels between cities with and without LEZ systems. Regarding studies on individual cities, similar identification complexities as in the case urban tolls arise. In particular, it is difficult to identify an unaffected area comparable to that affected by LEZ. As for the studies that compare cities with and without LEZ systems, the heterogeneity in the application of the policy is generally not taken into account, as the restricted area may range from a small part of the city to a wide area involving most of the city center. Undoubtedly, the aggregate effects of LEZ are conditioned by the extension of the restricted zone. Finally, as in the case of urban tolls, local drivers can anticipate the effective implementation of the policy and, consequently, adapt their habits in advance. Such accommodative behavior (typically based on a car renewal process) seems to be particularly relevant in the case of LEZ.

Keeping these limitations in mind, some studies examine the effectiveness of LEZ in abating pollution in German cities. In Germany, all vehicles (cars, buses, and trucks) are categorized into four mutually exclusive classes, depending on their PM10 emissions (as PM10 is often considered the most lethal air pollutant due to its capacity of penetration in the respiratory tract and bloodstream). Although German LEZ usually affect city centers, the boundaries of the restricted area, the implementation dates, and the precise types of banned vehicles vary across cities.

These studies for German cities adopt a diff-in-diff approach using panel data composed by cities, which are classified into two groups depending on whether the policy has been implemented. Malina and Scheffler (2015) analyze the impact of LEZ on the emission of PM10, finding a reduction of 13%. However, the authors themselves recognize the limitation of not being able to accurately measure the impact of the policy in surrounding areas. Instead, Wolff (2014) circumvents this limitation by using data at a smaller geographical scale and finds an average reduction of emissions in terms of PM10 of 9%, with a range that goes from almost zero in small cities like Tübingen up to 15% in cities like Berlin. Morfeld et al. (2014) also find a significant impact of LEZ in reducing NO, NO₂, and NO_x (limits on NO, NO₂, and NO_x were imposed in Germany since 2010 as they were proved to be a major traffic-related pollutant). However, the impact is modest, being 4% at most.

Some other studies analyze the effect of LEZ on individual cities by comparing pollution levels before and after their implementation. Panteliadis et al. (2014) study the LEZ implemented in Amsterdam, which gradually banned heavy-duty vehicles based on their emission category. They find a reduction in the concentration of different pollutants, ranging from 4% in terms of NO₂ and NO_x up to 10% in terms of PM10. Ellison et al. (2013) study the case of London, where an emission standard was imposed on trucks, coaches, and buses in an area covering most Greater London. They show that PM10 concentrations within the limits of the low emission zone dropped by 2.46%–3.07% as compared to a lower decrease of 1% in limiting areas; however, no discernible differences are found for NO_x concentrations. Cesaroni et al. (2012) analyze intervention policies in Rome, including the exclusion of all cars from the historical city center and the prohibition of old diesel vehicles within the railway ring. In the intervention area, they find a PM10 and NO₂ reduction of 33% and 58%, respectively (but the results are modest city-wide). It is important to acknowledge that the latter two studies do not employ any econometric techniques allowing controlling for potential confounders like weather.

Although the main goal of LEZ is to reduce pollution, an impact on congestion can also be expected given the strong positive relationship between both externalities. Only Bernardo et al. (2018) provide a direct test on the effect of LEZ on congestion by using data of large European urban areas over the period 2008–16. As in the mentioned studies for Germany, they adopt a diff-in-diff approach using a panel data composed by cities affected and unaffected by the policy. They find that urban tolls (and, to a lower extent, bike-share systems) can be effective in mitigating congestion. Instead, LEZ are ineffective, with the exception of urban areas having a high proportion of old cars before their implementation. Thus, LEZ seem to be applied in European cities with renovated car fleets and, consequently, they cannot have substantial effects in reducing traffic and congestion. This observation suggests that pollution (and not congestion) is the main policy objective for most European cities. An additional reason explaining the preference for LEZ would come from the unpopularity of urban tolls, which are perceived as new taxes.

Conclusion: LEZ Versus Congestion Tolls

From a theoretical viewpoint, there is a wide consensus among economists on the advantages of congestion tolls to confront car-related negative externalities. The main argument is that the price-based measures induce a more efficient use of existing infrastructures, while generating additional revenues. By contrast, LEZ can be expected to be inefficient as they reduce demand indiscriminately, that is, independently of drivers' willingness to pay.

Furthermore, LEZ can have regressive effects as they harm lower income drivers, who typically own older and more polluting cars that do not meet the emission standards. Instead, tolls may be more redistributive as they raise funds that are typically used to improve public transportation.

Regarding the effectiveness of both policies, the empirical evidence shows unambiguous effects associated with congestion tolls in mitigating both congestion and pollution. As for LEZ, the existing studies suggest that, although they may be effective in abating pollution (at least in the short term), they are not effective in reducing congestion.

All in all, urban tolls can be seen as a superior tool as they mitigate simultaneously pollution and congestion. However, tolls are applied in few cities while LEZ are massively implemented in European cities. The reason behind the underuse of tolls has to do with their unpopularity, as they are perceived as new taxes the citizens have to pay for a service that used to be free.

Introduction

The direct consumer welfare impact of transport infrastructure projects is often estimated based on the outputs from a traffic model. Using the so-called rule-of-a-half (ROH), the change in consumer surplus—the user benefits—is calculated using the changes in travel times and costs and the number of trips before and after the project together with externally decided unit costs for the value of time and travel.

The change in consumer surplus measures the aggregate willingness to pay for the change in the transport system that the project generates. Often the transport project provides reduced travel times due to, for example, opening of new roads or bridges, but other types of transport projects can also be considered, for example, change in the frequency of public transport, or introduction of road taxes.

The change in consumer surplus measures the direct benefits to travelers from changes in accessibility. When markets are perfect, this is equal to the total welfare effects of accessibility changes (Jara-Diaz, 1986). Other welfare effects, for example, environmental impacts or the cost to tax payers, are typically just added.

The consumer surplus for an individual traveler is the monetary value of the utility of travel. For example, the utility of a trip is often specified as the utility associated with reaching the destination, less the utility cost of the trip. The utility cost includes both monetary and nonmonetary costs (e.g., time costs).

An alternative method of calculating the user benefits is available when the traffic model is a random utility discrete choice model. In that case, the individual consumer surplus is available within the discrete choice model. Many traffic models build on the nested logit model. In this model, the consumer surplus can be calculated in terms of the so-called logsum.

Discrete Choice Models

Traffic models typically consider the travelers' choice of destination, transport mode, and route. Each dimension is treated as a choice among a finite number of mutually exclusive alternatives, using an additive random utility discrete choice model.

Each choice alternative has an associated utility that accounts for both the attractiveness of options and travel costs. Travel costs include not only monetary costs but also different aspects of travel time. Each traveler chooses the alternative that gives him or her the highest utility.

Travelers have different preferences and therefore end up making choices that are distributed across the choice alternatives. Some heterogeneity can be accounted for via observable differences in, for example, socioeconomic characteristics. Importantly, the model also allows differences in preferences that are not related to observable characteristics. These differences in preferences are random from the perspective of the modeler. As a consequence, the consumers' choices are predicted only as probabilities.

We now proceed to presenting this in a formal model.

Discrete Choice and the Additive Random Utility Model

Consider a consumer with random utilities

$$u_i = v_i + \varepsilon_i, i \in J \quad (1)$$

associated with the alternatives in a finite choice set J , for example, comprising combinations of destinations, transport modes, and routes. v_i is a deterministic part of the utility function while ε_i is a random part determined by factors unobservable by the modeler. The random part ε_i is independent of v_i and is absolute continuous with finite means and full support. We assume for simplicity that utility is money-metric such that we can ignore the translation of utilities into monetary units, as $\frac{\partial v_i}{\partial p_i}$ is constant and equal to -1 .

The consumer chooses the alternative that maximizes his or her utility. The expected maximum utility (across a population of consumers) is given by:

$$G(v) = E \left(\max_i (u_i) \right). \quad (2)$$

$G(v)$ is the expected utility that an optimizing consumer will attain when faced with a given choice set. In the case when the choice includes alternative travel destinations, the expected maximum utility can be viewed as a measure of the accessibility of the collection of travel destinations. To understand this, we first need to discuss what an accessibility measure is.

Accessibility Measures

“Accessibility concerns physical and temporal constraints on behavior and thus is an aspect of the freedom of action of individuals” (Weibull, 1980). In a spatial context, accessibility depends on the number of opportunities for spatial interaction and on a concept of geographical distance. Accessibility can also be defined more generally in a microeconomic choice context where choice alternatives are associated with different levels of attraction and some general concept of distance or proximity. We may say that the accessibility of the set of choice alternatives increases if the alternatives become more attractive or if the distance decreases. An increase in accessibility is seen as a benefit and it is often used as a goal for, for example, planning policies.

An accessibility measure is now a function that attributes a finite and nonnegative real number to any set—or configuration—of opportunities, where the opportunities are defined as the pair of the distance to—based on the chosen distance concept—and the attraction of the alternative (Weibull, 1976). Weibull presents an axiomatic framework for basic properties that such a standard accessibility measure should have (Weibull, 1976, 1980). These properties are of technical as well as of interpretational character.

An accessibility measure should satisfy the following six conditions:

1. The order of the opportunities in a configuration does not affect the accessibility measure;
2. The accessibility measure should be nonincreasing in distance and nondecreasing in the attraction of each alternative;
3. The accessibility measure evaluated at zero distance should be continuous and increasing;
4. A single opportunity with infinite attraction at zero distance is better than any pair of opportunities with finite attractions;
5. Any opportunity with zero attraction should not contribute to the accessibility measure; and
6. When two configurations are equally accessible then adding the same new opportunity to both configurations will not change the equivalence.

Accessibility measures can have different forms. Typically, accessibility measures are separable in opportunities; each opportunity is assigned a numeric value and these are then aggregated into a single aggregate numerical value. The aggregation is often additive but other forms can also be used. The additive indicators are typically seen in the traditional gravity models. Another type of indicators is the maxitive indicators that are inspired by microeconomic theory and where the attractiveness of an alternative is the utility of the choice, and where consumers only choose one alternative: the one that maximizes his/her utility.

While the axiomatic framework of Weibull ensures that the accessibility measures have desirable properties, it does not necessarily ensure a behavioral foundation or a link to consumer benefits, and hence it can be difficult to interpret their values. To ensure interpretability, an accessibility measure should be closely related to the benefits of the choice system (e.g., in utility or monetary terms). In this respect, following Ben-Akiva and Lerman (1985), the expected maximum utility function in (2) can now be interpreted as an accessibility measure; it satisfies the six conditions and directly measures the benefits and costs of the choice system in terms of utility and, as utility is assumed money-metric, in monetary terms.

For the subutility v_i , the attraction of choosing alternative i is the benefits that this choice of, for example, travel destination will give the consumer, while the distance of the alternative is given by the costs of reaching the alternative, for example, in terms of monetary and time cost of traveling to a given destination.

The Demand Curve

Having connected discrete choice models to the notion of accessibility, we now continue with deriving the consumer surplus based on the discrete choice model in (1). It will turn out that a change in expected maximum utility can be interpreted as a change in the

Marshallian consumer surplus corresponding to the discrete choice model. We first note that, for the discrete choice model in (1), the probability that a consumer chooses a given alternative i is equal to the derivative of the maximum expected utility of the discrete choice model, that is:

$$P_i(v) = \frac{\partial G(v)}{\partial v_i} \quad (3)$$

This result is known as the Williams–Daly–Zachary theorem (McFadden, 1978).

In a population of consumers with identical observable characteristics, the choice probability is equal to the market share of the alternative i . Hence, the demand curve is given by:

$$D_i(v_i) = \frac{\partial G(v)}{\partial v_i} \quad (4)$$

Demand curves are typically expressed in prices and our demand curve can easily be translated:

$$D_i(p_i) = \frac{\partial G(v)}{\partial v_i} \cdot \frac{\partial v_i}{\partial p_i} = -\frac{\partial G(v)}{\partial v_i} \quad (5)$$

The price, p_i , is understood as the full cost of the alternative, including both monetary and nonmonetary costs and in particular time costs. The coefficient $\frac{\partial v_i}{\partial p_i}$ equals -1 as utility is assumed money-metric.

This demand curve can now be used to calculate the consumer's surplus.

The Marshallian Consumer's Surplus

The Marshallian consumer surplus is a classic benefit measure in microeconomic theory. The change in consumer surplus measures the benefit to the consumers of a change in the prices that the consumers are facing. It reflects the monetary compensation that a consumer should receive in order to be indifferent with the change in prices. The change in the Marshallian consumer surplus can be calculated as the value of the area to the left of the demand curve D for the given price change from p^0 to p^1 (Mas-Colell et al., 1995).

$$\int_{p^1}^{p^0} D(p) dp$$

This is illustrated in Fig. 1.

The Marshallian consumer surplus is a convenient welfare measure as it translates utility into willingness to pay that facilitates comparisons of projects as well as comparisons across individuals.

Small and Rosen (1981) show that calculating the change in the consumer surplus as the area to the left of the demand curve also applies when demand is given by a discrete choice model.

We can therefore rewrite the expression for the Marshallian consumer surplus in terms of our discrete choice model in (1).

The Use of Consumer Surplus in Project Evaluations

If a project improves alternative 1 by increasing v_1 from v_1^0 to v_1^1 then the change in utilities can be measured with the change in the Marshallian consumer's surplus.

$$\int_{v_1^0}^{v_1^1} D_1(v_1, v_2, \dots, v_j) dv_1 = \int_{v_1^0}^{v_1^1} \frac{\partial G(v)}{\partial v_1} dv_1 = G(v_1^1, v_2, \dots, v_j) - G(v_1^0, v_2, \dots, v_j) \quad (6)$$

Figure 1 The change in consumer surplus as an area under the demand curve.

We see that when demand is given by the discrete choice model then the change in the Marshallian consumer surplus is the change in the expected maximum utility function, G . As we saw earlier, this change in the expected maximum utility can be interpreted as the change in accessibility, and hence the change in the Marshallian consumer surplus can be interpreted as a change in accessibility. With this formulation the measure of accessibility has a clear connection with the utility and hence is easily interpretable.

Rule-of-a-Half

In many practical applications, the change in consumer surplus following a project is computed using the following linear approximation of the demand function:

$$\int_{v_1^0}^{v_1^1} D_1(v_1, v_2, \dots, v_J) dv_1 \cong \frac{1}{2} [D_1(v_1^1, v_2, \dots, v_J) + D_1(v_1^0, v_2, \dots, v_J)] \cdot (v_1^1 - v_1^0). \quad (7)$$

This is known as the ROH.

This expression easily translates into the similar formula expressed in price changes, which is convenient for many practical applications, where it is a change in prices that is considered.

$$ROH \cong \frac{1}{2} [D_1(v_1^1, v_2, \dots, v_J) + D_1(v_1^0, v_2, \dots, v_J)] \cdot (p_1^0 - p_1^1) \quad (8)$$

The ROH has many advantages in practical applications. It only requires that the modeler knows the demand before and after the project and the change in price for the affected alternative. Hence, neither the exact utility level nor the full demand curve needs to be estimated.

The approximation in the ROH is more precise the closer the demand function is to being linear. Hence, it works best for small project changes.

With the ROH, it is quite transparent what the source of benefits is, for example, whether they derive primarily from time savings or from savings in monetary costs related to trips. Similarly, it is easy to consider distributional effects, for example, across regions or across groups of travelers with particular modes.

Another advantage of the ROH is that the planner can use standard unit costs for values of travel time and for monetary costs related to a trip, which is mandatory in many official guidelines for transport project appraisal as it facilitates comparison of appraisals of different transport projects. In these situations the price will be expressed as a function of these unit prices and the distance d_i (e.g., kilometers or time use for a given choice of destination, $p_i = d_i \cdot \text{unit price}$).

For these reasons, the ROH is common in appraisal of transport projects. However, the ROH also has some disadvantages.

The derivation of the ROH as an approximation to the user benefit is generally most precise when projects are small and the demand function is close to linear. Furthermore, using the ROH to calculate user benefits ignores income effects. When transport costs do not constitute a major part of the household budget and if the changes in transport costs are small, this is again a fair simplification. Overall, this implies that the use of the ROH to calculate the user benefits works best for smaller policy changes.

Challenges using the ROH also arise when new alternatives are added to the consumers' choice set. This is the case when, for example, a new mode or a new trip destination is introduced. In this situation, if it is not possible to define a relevant base scenario with a finite price, then it is not possible to calculate a finite price change ($p_i^0 - p_i^1$), and hence the ROH cannot be calculated directly. An alternative is then to calculate the change in consumer surplus directly by using an accessibility measure, as the expected maximum utility function G in (5), where the utility effect from a new alternative can easily be included. This is especially convenient when the choice models are of the logit type. We will illustrate this in the following.

However, while using the standard ROH assumes that the demand function can reasonably be estimated and assumed to fit the linear approximation; the use of expected maximum utility function assumes that the specification of the original utility function in (1) holds. This is more difficult to test.

Logsums

We consider now the special case, where the random utility model is a logit model. For logit models, the expected maximum utility function G has the convenient form of the so-called logsum. When this is used to calculate the change in the consumer surplus it is called the logsum approach. This will be presented in the following.

In a logit model, the market share of alternative i , the demand, is given by:

$$D_i(v) = \frac{e^{v_i}}{\sum_{j \in I} e^{v_j}}. \quad (9)$$

The expected utility of a given set of alternatives is given the logarithm of the denominator, known as the logsum:

$$G(v) = \ln \left(\sum_{j \in J} e^{v_j} \right). \quad (10)$$

The change in consumer surplus is now given by the change in the logsums:

$$G(v^1) - G(v^0) = \ln \left(\sum_{j \in J} e^{v_j^1} \right) - \ln \left(\sum_{j \in J} e^{v_j^0} \right). \quad (11)$$

The logit model is used in many traffic models. When using the logsum approach the problems of assuming linearity of the demand curve as well as the problem of considering new choice alternatives are handled. It is straightforward to add or remove alternatives from the choice set in the calculation of the logsum, so using this to compute the effect on welfare is simple. It is also easy to see that adding a new alternative will always lead to a welfare improvement.

Conclusion

Within a discrete choice model, and specifically within a logit model, a change in consumer surplus can be interpreted as a change in accessibility—the potential of opportunities for interaction. Moreover, the accessibility measure is directly linked to utility and changes in accessibility can directly be interpreted as changes in expected utility.

Relying on the discrete choice model structure to compute welfare effects has much appeal for applications. On the contrary, relying on the ROH allows one to be agnostic about the underlying model, and it facilitates the use of standard unit values and, more generally, comparisons of projects that are appraised using different traffic models.

Introduction

Producer surplus is a concept that is often mentioned in discussion of production and transaction. In particular, it is an important component in cost–benefit analysis (CBA). In this article, we explore producer surplus in a few steps. First, we start with giving the general definition of producer surplus commonly found in economics textbooks. Due to the nature of the transport market, it is of interest to discuss how the concept of producer surplus is applied to the transport sector. More specifically, we look into the producer surplus for transport infrastructure providers and public transport operators. The next step is to consider a bigger picture and see how producer surplus relates to transport policies and fits into the wider objective of welfare maximization. We also discuss some factors affecting producer surplus. Lastly, the future trend of producer surplus is outlined.

Note that two assumptions will hold in this article unless specified otherwise. First, it is assumed that perfect competition prevails (this holds for both transport market and other markets because it is a common practice to assume zero-profits for firms in sectors other than transportation in transport CBA; to be relaxed later); second, we focus on partial equilibrium in the transport sector and ignore the distortions in other markets.

Definition of Producer Surplus

In a market, trade can potentially occur when there is a divergence between consumers' valuation and producers' production cost of a unit of good. Assuming zero transaction costs, total gains or surpluses from trade are simply this divergence, summing across units of the good traded. The rationale is that when the downward-sloping demand (maximum willingness to pay of consumers) of the unit of good exceeds the production cost the producers have to pay, both consumers and producers will gain by trading until the marginal valuation and the marginal production cost equals. This output is the competitive equilibrium level of output, which maximizes total surplus. And this total surplus is shared between consumers and producers. How this total surplus is shared between both parties will depend on the market price of the good, and the market price will in turn depend on the form of demand and cost functions.

A second way to express the concept of producer surplus is that it is the producer's revenue minus the production cost. Algebraically, it is $PQ - TC(Q)$, where P is the price of the good, Q is the quantity of the good, and TC is the total production cost of Q units of the good. $TC(Q)$ can be represented in two ways: (1) the product of average cost and quantity of the good $AC \cdot Q$, and (2) summing the marginal production cost over the units of the good $\int_0^Q MC(f)df$. Diagrammatically (**Fig. 1**), the most common representation of producer surplus in a demand-supply diagram is the shaded inverted triangle that corresponds to the expression $PQ - \int_0^Q MC(f)df$ (while the mirror triangle under the demand curve is the consumer surplus). Alternatively, the rectangular area outlined in blue corresponding to the expression $PQ - AC \cdot Q$ also represents the producer surplus.

The expressions of producer surplus consist of revenue and cost. The revenue is mainly driven by market structure that the producers face. On the other hand, the cost is governed by the cost structure of the production of the good or service. In **Fig. 1**, the marginal cost curve is upward sloping, meaning that the production cost for an extra unit of the good is increasing. The production cost might as well be decreasing or constant, at different scale of production, depending on the production function. See **Fig. 2** for example. The marginal cost is the slope of the production cost, while the slope of the ray (connecting the origin and the point on production function) is the average cost of production. In this example, the marginal cost of production is decreasing at lower

Figure 1 Producer surplus (horizontal AC).

Figure 2 Producer surplus (U-shaped AC).

production level (below Q_0) and increasing at higher production level (above Q_0). The corresponding producer surplus at production level Q^* is shaded.

In fact, whenever there is a divergence between price and marginal cost (given that perfect competition prevails), a Pareto improvement is possible such that the total surplus (producer surplus, PS + consumer surplus, CS) can be increased. However, it does not necessarily mean that a total surplus increase will lead to a Pareto improvement because the loss of one party can be compensated by the gain of the other. This is inconsistent with the definition of Pareto improvement.

It is clear that the size of producer surplus depends on the cost of production. However, what is unclear is what components of production costs are included in the calculation of producer surplus. Producer's optimization problem is to maximize producer surplus, denoted by $\text{Maximize}[PQ - TC(Q)]$. Assuming no entry and exit of the market, the decision to be made is the production level. By differentiating the expression with respect to production level and set the derivative to zero, we obtain the well-known expression of $MR = MC$, which gives the optimal level of production. This equality holds regardless of the components of the total cost of production. It follows that including a fixed cost of production (which is independent of the production level) does not affect producer's decision on production level as long as he produces but the size of producer surplus is affected. The literature is not very clear on the inclusion of fixed costs. One way out is to differentiate the short-term producer surplus (gross profits without fixed costs) and long-term producer surplus (gross profits minus fixed costs). See the entries "cost functions for road transport" and "operation costs for public transport" for more discussion on production costs in a transport context.

Note that the definition of producer surplus is equivalent to the definition of profit here. We use the two terms, producer surplus and profit, interchangeably. While profit is defined as being windfall in nature in some economics texts, we do not follow this definition in our discussion.

Specifics in the Transport Market

The following discussion specific to the transport sector is valuable because the transport market is different in a few ways: first, the "product" in the transport market is trips, instead of a physical product; second, external costs of transport trips play an important role in determining the equilibrium in the transport market; third, perfect competition does not often prevail in the transport sector (in many cases of transport supply in reality, such as public transit provision and the provision of highway use, a large capital cost is invested to supply a certain capacity without extra variable cost. This results in natural monopoly due to decreasing average costs. Besides, some monopolies are results of government regulations); fourth, the investment in extra capacity does not necessarily

correspond to higher revenue. These differences, especially the third and fourth ones, make it worthwhile to discuss producer surplus in the transport sector specifically.

Producer Surplus in Highways (Driving and Road Use)

In theory, the decision of how much to produce in road transport is treated as a continuous variable that is completely flexible. In reality, this might not be the case as government regulations could be specific on specifications of road infrastructure. Here, we first consider the theoretical point of view and discuss the issues in practice.

Producer's optimization problem can be represented by $\text{Maximize}[\tau Q - \rho K(V_K)]$, where τ is the toll, V_K is road capacity, and the function K is the capital cost of capacity. Since road infrastructure lasts for many years, this fixed cost is annualized with the factor ρ . Analogous to a standard profit maximization problem, the producer chooses the level of capacity to maximize producer surplus but this is different from the standard profit maximization problem for a producer: the quantity of production (capacity) does not directly equate the quantity of consumption (trips). Instead, the capacity affects the number of trips through the generalized price of a trip $gp = P = c(Q, V_K) + \tau$, where c is the cost of the trip as a function of number of trips and capacity. Suppose that the producer can freely choose the toll. The producer's optimization problem requires the choice of both the price (toll) and the capacity. As a result, a pricing rule and an investment rule are to be satisfied to give the maximum producer surplus. This complicates the standard problem where usually each quantity corresponds to one price so deciding either will suffice.

In practice, the cost of infrastructure supply is often independent from the number of trips (users) made on the highway, and capacity choice is not entirely flexible (due to indivisibility). Once a highway has been constructed, serving an extra vehicle on the highway does not incur any extra cost (except for maintenance cost that is correlated to traffic volume). This is true until a certain limit that is constrained by the capacity of the highway. Recall that the cost of production that is constant over output is termed fixed cost. Since road infrastructure lasts for many years, this fixed cost is annualized, and compared to the revenue that the producer receives. Diagrammatically, the producer surplus is represented by a rectangle (in blue) bounded by the toll earnings (rectangle outlined in black, τQ^*) and the annualized infrastructure cost for capacity V_1 (in yellow) (Fig. 3). Note that, however (unlike the standard goods market), the cost of infrastructure (production) does not directly determine the equilibrium number of trips or the corresponding cost of road use. The cost of road use incurred by the users (AC) consists of the money cost of using the highway, and the nonmonetary cost including time cost of the trip. This is independent from the production or construction cost of the highway unless tolls are charged such that the revenues can cover the costs.

It is also common that negative producer surpluses are found in road infrastructure projects. Users are either not charged for road use or the tolls are not high enough to cover the infrastructure cost. This has been dealt with in different ways: (1) some countries (China, for instance) have a "maintain road by road" rationale so car users are charged in different ways such as road maintenance fees and registration fees. These revenues are used to pay for the negative producer surplus incurred in road projects. (2) Some countries (Germany, for instance) have earmarked other car use-related tax revenues such as gasoline taxes for road projects. Table 1 gives some examples on how different countries deal with car taxes (Fung and Proost, 2017).

It is worth pointing out that the United States has an increasing concern with decreasing gasoline tax revenues both at the federal level and the state level. On top of the fact that federal gasoline tax has not been adjusted since 1997, this is mainly due to the growth of electric vehicles and due to the better fuel efficiency of gasoline vehicles (Fisher and Wassmer, 2014). The gasoline tax revenues may not be able to cover the negative producer surpluses incurred in highways.

Certain variable costs are incurred in the production of trips on highways. An example is the maintenance cost of highways. Since maintenance cost increases with the frequency of road use by heavy trucks (number of trips), we call this a variable cost. In the

Figure 3 Producer surplus (highways).

Table 1 Car taxes

Country/ region	Federal gas tax	Federal car ownership taxes or other taxes	State gas tax	Parking fees and local tolls	Use of federal gas tax money
United States	Low—not changed since 1997	Low; taxes on tires, vehicles	Varies by state	Parking fees Occasional for public works	Redistributed to states; earmarked for highways and mass transit
China	Increased in 2009 but still low	Low; vehicle purchase tax (10%)	No	Parking fees Tolls on commercially operated toll roads; tolls on government roads in the western provinces	Redistributed to regions; by law reserved for infrastructure
EU	None but high minimum excise	None	Varies but tax competition limits increases	In some countries and cities (maximum average toll for member states)	Varies by country
Germany	High	Low; VAT (19%)	No	Parking fees Occasional urban traffic restrictions for air pollution—no tolls	By law reserved for infrastructure
Switzerland	High +	Federal vignette for highway use; VAT (8%), acquisition tax (4%)	No	Parking fees; provincial annual motor vehicle tax	Earmarked for road construction and maintenance

Source: Modified from [Fung and Proost, 2017](#).

computation of producer surplus, both fixed costs and variable costs are considered. But sometimes fixed costs are excluded because fixed costs do not affect the equilibrium; only the value of producer surplus is affected.

Producer surplus of highway capacity provision may not be relevant in many cities as the government is often the producer and its objective is often not maximizing producer surplus but instead maximizing welfare. In this case, producer surplus is then at the same footing as the consumer surplus.

Producer Surplus in Public Transit Supply

Producer surplus in public transit supply has its similarity to producer surplus in road infrastructure provision: the capacity that the producer invested in does not have a direct connection with the number of transport trips. Instead of investing in road capacity, public transport service providers invest in capital such as vehicles and drivers that results in service frequencies. The public transport service provider's optimization problem can be formulated as $\text{Maximize}[\tau Q - Kf]$ where τ is the fare, f represents the frequency of the service, and K represents the cost of service provision per frequency. It follows that the PT service provider chooses both service frequency and fare to maximize producer surplus.

The fixed cost in public transit varies among the modes: for buses, the fixed cost contains hardware such as capital cost of bus stops and capital cost of vehicles (this does not change with the number of passengers within its capacity); for other modes such as train, metro, or BRT, the fixed costs are considerably higher because the infrastructure cost such as costs of tracks are included. Just as road infrastructure, these costs for infrastructure that are durable are annualized over the period of use.

Bus

The surplus of a bus service provider is simply the total fare revenue minus the cost of bus service provision. The fare revenue depends on the fare structure such as the differentiation between peak and off-peak fares and the availability of concession schemes and monthly passes. On the other hand, the cost of service provision includes the cost of bus stops, wage of drivers, and fuel cost (fuel tax included). The service provider can set the fares and frequencies to maximize its surplus but there are often constraints in reality: there can be government regulations on the spacing of bus stops and bus accessibility of residents so frequency has to be above a certain level. It is also not uncommon for government to intervene in the fare setting of buses and avoiding time-varying fares to avoid confusion. Moreover, wages of drivers and service frequency can be influenced by unions, as they demand a certain income level for the union members. The authority may pressure the PT provider to reach a higher patronage for political reasons. These constraints affect the resulting producer surplus and producer surplus might even be negative when the costs cannot be covered by the revenues.

Analogous to the number of car trips, the number of bus trips is only determined by the service provision indirectly through the generalized price of a bus trip. The components of the generalized price of a bus trip such as in-vehicle time cost (augmented by discomfort) and waiting time are affected by frequency while the access cost to bus stops is affected by the supply of bus stops (spacing).

Train/BRT

Most of the earlier discussion on producer surplus of bus service provider is applicable to train or BRT providers but there are exceptions. First, the costs involved in providing rail or BRT service are much higher than those for bus service. The infrastructure cost of train stations, tracks, and rolling stocks are often so large that breaking even is almost impossible over the service period. In Belgium, a diabolito fee is added on top of regular train fares for some routes to pay for the construction of rail infrastructure. In some countries such as Sweden, a track charge is imposed on train operators according to the distance and weight of the trains. The former increases producer surplus, while the latter reduces producer surplus of the train operators. Note that in reality it is barely the case that the rail markets are under perfect competition; they have some monopoly power due to government regulations or natural monopoly. As a result, producer surpluses are often positive for these rail operators.

(Optimal) Producer Surplus and Subsidies—Why is Negative Producer Surplus Possible?

When we consider the expression of producer surplus (=revenue – cost), it is obvious that the negative of this expression (cost – revenue) is actually the subsidy of service provision. But at this point, a question arises: why would the producer surplus be negative in the first place? Why is the producer willing to provide the service for a negative producer surplus as the service provider is better off by exiting the market? The answer is the availability of subsidy so the negative producer surplus (loss) can be compensated. These subsidies are often provided by the government.

Another question follows: why do we need subsidies for transport service provision? The reason is that subsidy can be justifiable from a welfare point of view. Instead of having a profit-maximizing producer making the decision on service provision and the prices, we compare the profit-maximizing level of service provision and prices with the welfare-maximizing level of service provision and prices. The welfare concerning the transport market can be represented by $W = CS + PS - \text{ext} - \text{MCPF}(\text{subsidy})$, which is the sum of consumer surplus, producer surplus minus the externality and the marginal cost of public funds related to the use of subsidy. The optimal level of service provision and the optimal prices can be obtained by maximizing welfare. We could see that producer surplus is only one of the terms of the welfare expression and therefore it is unlikely that the profit-maximizing level of service provision and prices coincides with the welfare-maximizing levels. With the optimal prices and level of service determined, the optimal amount of subsidy can be calculated. In other words, there is a corresponding amount of producer surplus that is optimal (and maximizes welfare). This is the approach in [Börjesson et al. \(2017\)](#).

Optimal level of subsidies can also be perceived as a policy instrument. The authority sets the percentage of subsidies (of operating cost) and optimizes the other variables such as fares and frequencies. This is the approach in [Basso and Silva \(2014\)](#).

Note that in the previous discussion, we implicitly assume that transport service provision is managed by an independent profit-maximizing provider. This is not entirely unrealistic; in Britain, the rail service is operated by private companies. In Hong Kong, some tunnels adopt the BOT (Build-Operate-Transfer) model where the private companies build the tunnel, operate the tunnel and charge the use of the tunnel up to a certain contract period, and transfer the ownership back to the government. This is one of the ways for the government to not lose all control over the infrastructure and yet ensure that the private companies can cover their initial investment (which is probably very high) by operating and charging the service involved.

Despite the simple economic principle behind optimal subsidies, different governments tend to have very different policies and thus actual subsidy amounts vary greatly. [Table 2](#) shows the actual subsidies found in major cities (recovery rate of public transport operating expenditure by farebox revenue).

Producer Surplus and Mode Choice

Another crucial determinant of optimal producer surplus (subsidy) is mode choice. One of the common arguments for providing public transit subsidies is to divert drivers from their cars to public transit so as to reduce congestion. Public transit subsidy is justifiable as long as congestion is serious enough and enough drivers are diverted to public transit. The measure of cross-price elasticity of demand is a good indicator of how many drivers will be diverted to public transit when the fare decreases. A similar indicator is the diversion factor of cars when public transit fare changes. This diversion factor is a fraction that represents, for instance, how many of an extra bus passenger would have been car driver previously. It ranges from 0.29 to 0.25 for rural areas and metropolitan areas, respectively ([Wardman et al., 2018](#)).

Table 2 Recovery rate of public transport operating expenditure by farebox revenue

City	London	Manchester	Milan	Munich	Oslo	Paris	Stockholm
Urban population density	54.9	40.4	71.7	52.2	26.1	40.5	18.1
Recovery rate	81.2	96	41.7	64.4	63	45.5	54.3

Source: Modified from EU database.

It is important to note that producer surplus of the public transit may not be equivalent to the subsidy of the transport sector as the public transit may be cross-subsidized by the revenues from charging car use, such as tolls and fuel tax revenues.

Producer Surplus and Density

It is believed that different cities have varying amount of subsidies and one of the reasons is the difference in population density. Population density affects both the total fare revenues and the cost of public transit provision. It is logical that public transit is more intensively used and has better coverage for areas with higher population density so the patronage is higher. But it is unclear whether the actual public transit fare is higher in more densely populated areas. There is no evidence that fares in low-density areas and high-density areas vary greatly. If the optimal public transit fare is considered, it can be shown that the optimal fare is higher in more densely populated areas. This is due to the higher level of externalities such as congestion in-vehicle (crowding) and congestion on roads.

The cost of public transit provision is higher in absolute amount in densely populated areas because of the higher frequencies needed. But it is likely that the per passenger cost is lower in densely populated areas. With a higher per passenger fare and lower per passenger cost, it is clear that there is a lower public transit subsidy needed in a densely populated area. More specifically, in an optimal setting, where public transit fare and frequency are optimized, the optimal subsidy is indeed lower for densely populated areas. The reason is that the optimal frequency is governed by the square root rule so public transit provision cost increases less rapidly than the optimal public transit revenue. In reality, in a suboptimal equilibrium, it is unclear that there is a strong positive relationship between population density and public transit subsidies.

Current Trend of Producer Surplus

With the recent technological advancement in the transport sector, we do not know how producer surplus will change. Developments such as the emergence of autonomous and electric vehicles (automobiles and buses) will likely lower the production costs because both the cost of drivers (wages) and the fuel tax payment will be lower (given that the capital cost increase is not too high, as these new vehicles may be replacing existing fleet that needs replacing anyway). On the other hand, the revenue of public transit supply may be higher or lower. This is due to the following changes.

First, the rise of sharing economy such as the rapid gain in popularity of services such as Uber (share) or ride-sharing apps on smartphones definitely provides a better match for consumers in terms of the origin-destination and timing of their rides. The trips made using these new services can be generated trips or trips that are diverted from more traditional modes such as cars and public transit. The amount of public transit fare revenue will decrease and the producer surplus for public transit operators can increase or decrease depending on the relative magnitude of revenue decrease and cost decrease.

Second, the growth in popularity of modes such as cycling, shared bike, and shared scooter has a similar effect as the growth in shared cars in terms of the diversion of car trips and public transit trips. However, there are two differences: first, the patronage of public transit might increase or decrease because the convenience and accessibility of bikes and scooters can be complementary to public transit access. More passengers can access public transit more easily by using the shared bikes and scooters. Second, the rise of these new modes is likely to decrease the transport-related taxes (for cross-subsidization of public transit) because bikes and scooters are cleaner modes. Charging these modes will be almost infeasible politically and practically.

Introduction

Cost–benefit analyses (CBAs) are the most popular method for assessing the economic merits of public projects in general and infrastructure projects in particular. The purpose of a CBA is to inform decision-makers of the economic merits of a given intervention/project relative to the status quo (i.e., a “do nothing” scenario) and against other competing interventions/projects. The popularity of CBAs among decision-makers in the public sector is due to the ability to aggregate benefits and costs into a single measure in monetary terms. Money is an aggregate measurement that everyone (i.e., the public at large and the decision-makers themselves) can easily relate to and agree upon.

Despite the fact that CBA is a popular method for assessing the economic merits of infrastructure projects, the question remains as to whether it is robust as a decision-making tool. Here, robustness is defined as the ability of a CBA to withstand or overcome adverse conditions and/or variations in input parameters. The problem of CBAs’ robustness becomes an issue when one considers how it is used in the decision-making processes. Take for example, the case in which CBAs are used to rank transportation projects for resource allocation purposes. In such a case, a league table is produced in which projects are ranked according to their economic merits, whereby those with the highest economic returns are ranked highest, which is consistent with the economic theory of maximizing the net benefits of projects. The problem is that the rankings (league tables) are done on the basis of point estimates of CBA alone. Therefore, uncertainties regarding those estimates need to be revealed to ensure that CBA-based decision-making is robust. If the range of uncertainties is wide, it might have been possible to rank projects in completely different order than those obtained from point estimates. It is therefore imperative that if informed decisions are to be made on the basis of CBAs, analysts must attempt to estimate the level of the inherent uncertainties. Otherwise, CBA will lose its reputation as a robust decision-making tool. Furthermore, decision-makers, analysts, transportation planners, and the public at large all need knowledge about CBAs’ degree of robustness as a decision-making tool.

In this paper, we address the robustness of CBA as a decision-making tool in the transportation sector. In the next section, we summarize the workings of CBA. In the third section, we assert that the robustness of CBA depends on the context in which it is to be used and that there are different forms of CBA. We present a matrix to explain for what types of decision the different forms of CBA can be considered robust. In the fourth section, we address the most common and major sources of uncertainties in CBAs. In the fifth section, we briefly discuss the paradox that a CBA can be a source of bias itself. In the sixth section, we argue that ex-post evaluation is a good way of testing the robustness of CBAs. In the seventh section, we discuss the robustness of CBA from the perspective of the future, and, in the eighth and final section, we present some concluding remarks.

The Workings of CBA

Decision-makers in the public sector and the transportation sector in particular rely on the expected benefits and costs that a given intervention (e.g., the realization of a given transportation project) should generate throughout its lifetime when making their decisions. It is in this respect that CBA became popular as a decision-making tool because it aggregates benefits and costs into a single

measure of intervention/project worthiness and that measure is in monetary terms—a rule of measurement to which everyone can easily relate.

A CBA proceeds by first evaluating the expected change in the benefits and costs of an undertaking compared with the “do nothing” or “do the minimum” option, and all of the benefits and costs are measured in monetary terms. For example, in the case of a new road project, the monetary benefits and costs include travel-time savings, reductions in accident costs, vehicle operating costs, environmental impacts such as increased/reduced noise from vehicles, and the investment and maintenance/operational costs of the road network. The next step in a CBA is to compare the discounted monetized benefits with the discounted costs. The result of such a comparison is the net present value (NPV). If the NPV is positive, the project will be considered to be profitable from a socioeconomic perspective because its benefits will exceed its costs; otherwise, the project will be deemed unprofitable. Formally, the NPV is expressed as:

$$NPV = \sum_{i=1}^t \frac{\text{Benefits} - \text{Costs}}{(1+r)^i} \quad (1)$$

where *Benefits* is the sum of changes (measured in monetary terms) in travel time, number of accidents, vehicle operating costs, and so forth; *Costs* are the sum of investment costs and changes in operational and maintenance costs; *t* is the economic life period of the project; and *r* is the discount rate. Hence, $(1+r)^t$ is the discount factor.

Another advantage of CBA as a decision-making tool is that it can be used in the selection of the most profitable projects from a pool of projects when government investment funds are limited. In such cases, the CBA rule states that projects should be ranked according to the value of their NPV divided by the financial costs of the project provided through government funds/budgets (NPV–cost ratio). Formally, NPV–cost ratios are calculated as:

$$NPV - \text{Cost ratio} = \frac{NPV}{\text{Budget cost}} \quad (2)$$

If, for example, the NPV–cost ratio is 0.20, the interpretation will be that the return from government/societal investment in the project will be 20%. In other words, for each dollar/euro invested, there will be a return of 20 cents.

Although CBAs are performed in the transportation sector in almost all countries in the Western world, the results are often criticized on the grounds that they may depend on uncertain assumptions about the future and other parameters included in the calculations. There seems to be a general concern among decision-makers and planners that the results of CBAs are very sensitive to small changes in parameters to the extent that they often lead to different policy recommendations and/or differences in project ranking. All of these concerns relate to how robust CBA results are relative to when and how they are used.

The Robustness of CBA is Contextual

The robustness of CBAs must be evaluated from the context in which they are used in relation to the different types of CBAs available. The contexts in which CBAs are used are normally grouped into the different planning and decision-making stages of a given project. In the transportation sector, the different planning/decision-making phases are: (1) a feasibility study of the project in which the decision to continue planning for a future final decision is made, (2) the selection of an appropriate project plan (alignment/alternative) to compete for funds with other projects, (3) resource allocation between competing projects from a pool of projects where resources are limited, (4) learning about the actual outcomes of the ex-ante CBA estimates used in the decision-making stage, (5) contributing to the improvement of ex-ante CBA, and (6) learning about the accuracy of the unit prices of impacts.

There are two main types of CBAs: ex-ante and ex-post CBAs. An ex-ante CBA is performed on the basis of forecasts before a project is realized (i.e., before the actual outcomes are known). By contrast, an ex-post CBA is performed at some point after a project has been implemented, when the outcomes are known to some extent. Both ex-ante and ex-post CBAs can be further divided into two basic classes depending on when they are conducted. For the ex-ante case, the two classes are the early project phase, when the decision to go ahead with planning is made, and in the detailed project phase, when the decision to select the appropriate alignment to follow and/or the decision to build is made. For the ex-post case, the two classes involve an evaluation at some point after the project has been implemented, which is also known as in medias res evaluation, and after the project has been implemented and terminated, which is the full ex-post evaluation.

Thus, there are many different planning and decision-making stages and several different types of CBAs, which indicates that one type of CBA may be robust as a decision-making tool in one situation and not in another situation. For example, in a detailed project, an ex-ante CBA may be robust with respect to the selection of project alignments/alternatives but not for learning about actual outcomes. In the latter case, an early ex-post (in media) CBA will be more robust. Hence, the robustness of CBA is contextual, meaning that it depends both on the type of decision to be made and the type of CBA available.

We have developed a matrix for comparing the robustness of the different types/classes of ex-post CBAs according to the different planning/decision-making stages. The matrix is presented in [Table 1](#).

To aid readers in understanding when in a planning/decision-making stage a given CBA is most robust, the gray-shaded cells in [Table 1](#) indicate when the different CBAs are robust as decision-making tools. For example, it is clear that the early project phase ex-ante CBA is not robust as a decision-making tool at any stage. This is because, at early stage CBA, very little is known about the

Table 1 The robustness of CBA by planning and decision-making stages

		Types of BCA			
		Ex-ante BCA		Ex-post BCA	
		(1)	(2)	(3)	(4)
No.	Type of decision	Early project phase ex-ante BCA	Detailed project phase ex-ante BCA	Early ex-post (in medias res) BCA	Full ex-post BCA
1	Feasibility of a project; decision to go ahead planning for different options for the same project	Not robust at all; in the early project phase many input variables are uncertain	More robust; more information is available and CBA is of improved quality	N/A: the project is already built and robustness of CBA is of no relevance at this stage of decision-making	N/A: the project is already built and robustness of CBA is of no relevance at this stage/ type of decision-making
2	Selection of alignments/ alternatives to compete for funds with others of a different project	Not robust at all; contains too little or no information of potential alignments. Uncertainties are too many with respect to input variables	Robust: more information is available and uncertainties are reduced. CBA is robust for selecting best alignment, especially if the uncertainties are expected to be the same across alignments	Very robust: if low sunk costs, CBA may recommend a change of alignment. If high sunk costs, not very useful as the recommendation is proceed with the alignment already chosen	N/A: it is too late as the alignment is already chosen and built. Robustness of CBA is of no longer relevant for this type of decision-making
3	Resource allocation between competing projects	Not robust; CBA contains too little detailed information; hence, uncertainties are large	Robust; CBA is very useful for allocating resources between competing projects. Uncertainties are expected to be equally distributed across projects	N/A: the resources are already allocated; hence, considering robustness of CBA is of little relevance	N/A: it is too late and the project is already built. Robustness of CBA is of no longer relevant for this type of decision-making
4	Learning about the actual outturn of ex-ante BCA estimates used at the final decision-making	N/A; no outturn data available	Not robust; high uncertainty about future benefits and costs	Robust; some outturn data are available—uncertainties are reduced	Very robust; uncertainties are at their minimum—but some difficulties in tracing changes that occurred may be a problem
5	Contributing to the improvement of Ex-ante BCA framework	N/A; too many uncertainties	Robust; but only as a basis for comparisons to ex-post CBA	Robust; but robustness increases if ex-post CBA is performed later	Very robust; but some errors may still go undetected
6	Learning about accuracy of unit prices of impacts that enter BCA	N/A; the accuracy of unit prices is not considered for this type of CBA	N/A; does not consider the accuracy of unit prices	Robust; only if the accuracy of unit prices is evaluated	Robust; only if the accuracy of unit prices is also evaluated

parameters that will be included in it and therefore it is full of uncertainties, rendering it not robust at all. By contrast, the detailed project phase ex-ante CBA is regarded as robust in many situations, as testified by the fact that it is among the most frequently performed CBA in the transportation sector. We find that it is robust in: (1) the feasibility study phase, because it assumes that detailed data are available, (2) selecting alignments/alternatives, (3) resource allocation between projects, and (4) contributing to the improvement of ex-ante CBAs, but only as a basis for comparison with ex-post CBAs. However, the detailed project phase ex-ante CBA is not robust with regard to learning about the actual outturns and learning about the accuracies of unit prices. The rest of **Table 1** is self-explanatory. We therefore conclude that no general conclusions can be made with regard to the robustness of CBAs, as robustness is contextual with regard to the problem in question and the CBA type available. Regardless of this conclusion, CBAs have certain major sources of uncertainties that may jeopardize the robustness of ex-ante CBAs, the type commonly used for decision-making. The major sources of uncertainties in CBAs are addressed in the next section.

Major Sources of Uncertainties in CBA

Having established that the robustness of CBA is contextual, we next examine the major sources of uncertainties in CBAs. Here, uncertainty is defined as the difference between the information (CBA results) that is required to make a reliable decision and the information available at the time of the decision-making. Thus, if the difference is small, the CBA will be robust.

Bearing in mind our matrix in **Table 1**, uncertainties mostly concern the ex-ante CBAs, whereas ex-post CBAs parameters and input data are known with more certainty. It should also be noted that the literature has demonstrated that ex-ante CBAs are the most

commonly performed type of CBA, whereas ex-post CBAs are seldom performed. The same literature has also classified the sources of uncertainties in CBA into the following three main categories: (1) uncertainties in parameters (unit prices), (2) uncertainties in cost estimates, and (3) uncertainties in traffic forecasts. In the next three sections, we discuss each of these uncertainties in turn, and relate them to the two typical decisions made in the transportation sector: determining the socioeconomic merit of a project and choosing a portfolio of projects from a pool of projects.

Uncertainties in Parameter Values/Unit Prices

In a CBA, parameters values/unit prices are the monetary values that are multiplied by volumes to derive impacts in monetary terms. An example is the monetary value of time that is multiplied by the volume of time savings to derive the monetary value of the total time savings. CBA also includes fixed parameters such as the discount rate that is used to discount future benefits.

Uncertainties in parameter/unit values can seriously jeopardize decision-making. As an example, assume a CBA is being performed according to Eq. (1) and in which benefits is the product of the value of time multiplied by the change in travel time for all car user. Assume further that the following values are yielded for a project: value of time per vehicle/hour = EUR 15; change in travel time per day = 10 min; traffic volume per day = 4000 vehicles; total investment cost = EUR 50,000,000; t (the economic life period of the project) = 40 years; and r (the discount rate) = 4%. Then, the annual value of benefits is calculated as: $15 \times (\frac{10}{60}) \times 4000 \times 364 = 3,640,000$ euros. According to these values, the NPV of the project will be:

$$NPV = \sum_{i=1}^t \frac{\text{Benefits}_i - \text{costs}_i}{(1+r)^i} = 19.8 \times 3,640,000 - 50,000,000 = 22,072,000 \quad (3)$$

where 19.8 is the discounting factor, with r (the discount rate) = 4% and $t = 40$. The project is regarded as profitable in socioeconomic terms because its NPV is positive, which implies that the benefit returns net of costs will be 22 million euros/dollars.

From the earlier results, the NPV-cost ratio according to Eq. (2) is:

$$NPV - \text{Cost ratio} = \frac{22,072,000}{50,000,000} = 0.44$$

This now implies that for every dollar/euro invested there will a return of 44%.

Next, assume that at the time of decision-making, the parameter value for time/value was falsely taken as EUR 15 when its correct value was EUR 10. In that case, reliable information was not provided for decision-making, since the NPV should have been: $NPV = 19.8 \times 2,426,667 - 50,000,000 = -1,952,000$ and the project should have been judged as not profitable. The NPV-cost ratio should have been -0.04 implying that the project will lead to a loss of 4% and not a gain/return of 44% per dollar/euro invested.

The question of how the uncertainties of unit values illustrated earlier would impact on the decision should be considered. In the case of judging the economic merit of a single project, uncertainties in unit prices would render a CBA ineffective as a decision-making tool, as it might lead to false conclusions regarding the merits of a project (i.e., whether the project would be profitable or not). In the case of selecting/ranking project portfolios from a pool of projects, uncertainties in unit prices might not distort the ranking/selection because unit prices used in CBAs are uniform across projects. In such a case, uncertainties in unit prices would act as shift parameter on all of the CBA results. Thus, the only problem in the second of the two cases is that nonprofitable projects may be falsely included in a portfolio, when transportation budgets are appropriated to a sector and must be used up. In a study that used Swedish data on transportation projects it was found that changes in unit prices did not alter project rankings (Asplund and Eliasson, 2016).

Uncertainties in Cost Estimates

The costs of constructing a new project are by far the biggest cost element in the appraisal of all transportation infrastructure projects. Hence, the estimation of costs requires careful consideration. If actual costs deviate from estimates, this will have a direct impact on the project's value for money as measured by NPV and/or the NPV-cost ratio. The problem with such deviations is that they lead to ineffective decision-making because false conclusions can be drawn about project worthiness. With regard to the selection of a project from a pool of projects, uncertainties in cost estimates are particularly problematic because they may lead to the selection of economically unviable projects and consequently to inefficient resource allocation. Compared with unit prices, uncertainties in cost estimates are project-specific and therefore they will have an impact on both the decision-making with regard to determining the economic merits of projects and the selection of a portfolio of projects. Hence, if the costs of some projects and not others are overestimated or underestimated, this can affect the ranking of projects.

A number of high-profile scandals have led many to question the reliability of cost estimates used in the CBAs of transportation projects: Denver International Airport opened 16 months late and cost the city USD 560 over budget; in Sweden, the Hallandsås Tunnel opened 19 years too late and cost 12 times more than originally planned; and the Edinburgh tram service opened GBP 375 million over budget and 3 years late. There are many other examples of transportation megaproject failures.

In some cases, overruns may be justified in order to accommodate changing needs that were not known ex-ante (i.e., at the time of decision-making, such as the necessary capacity expansions to cater for increased traffic). In such cases, increased costs may be accompanied by a corresponding increase in benefits. In other cases, overruns threaten both the economic viability of the project in question and the future of other public infrastructure projects. Thus, it may be concluded that the robustness of ex-ante CBAs depends greatly on the robustness of cost estimates. The robustness of cost estimates is also addressed elsewhere in this Encyclopedia.

Uncertainties in Traffic Forecasts

In addition to construction costs, the other main avenues through which bias can enter the CBAs in transportation projects are the traffic forecasts. If actual traffic deviates significantly from forecasts, this will ultimately affect the estimated economic benefits and, potentially, the ranking of projects, similar to the way uncertainties in cost estimates have an impact on CBAs.

The consequences of inaccurate traffic forecasts depend on the context within which the new facility is built. Historically, transportation projects have been justified on the basis of existing traffic alone, but large-scale road and rail projects may result in changes in travel mode, frequency of travel, distance traveled, destination, or a combination of all of these factors. In addition, in the long term, transportation projects may result in changes in land use through residential and commercial development. Omitting induced traffic from benefit calculations may thus lead to underestimations of the user benefits from a new transportation facility. In many cases, such as high-speed rail, fixed link projects or urban light rail, the purpose of investment is precisely to induce more people to travel in order to realize agglomeration benefits or urban regeneration.

However, if congestion is a problem or will become a problem during the appraisal period, underestimation of traffic may imply a shorter period of relief from congestion and hence an overestimation of benefits. Omitting induced demand can therefore bias the assessments of the economic viability of proposed projects, especially when there is a latent demand for more capacity.

Despite the crucial role of traffic forecasts, data limitations have meant that ex-post studies are relatively rare, but most of the studies that have been carried out have found that road projects have typically experienced more traffic than expected (Nicolaisen and Driscoll, 2014). A recent example is the widening of the M25 around Greater London, where hard shoulders on parts of the orbital motorway were converted to permanent additional running lanes in 2014. Within 1 year of opening, traffic growth was 10%–13%. An evaluation report found that the traffic increase over parts of the widened sections was greater than before the capacity improvements were made. However, if the scheme had not been built, journey times probably would have deteriorated further (Highways England, 2018). By contrast, the mean inaccuracy for rail projects is usually negative, as ridership often fails to meet expectations. A well-known example is the Channel Tunnel Rail Link, which connects the United Kingdom and France. The tunnel not only exceeded its budget by 80%, but passenger traffic was only one-third of what the project's promoters had expected. Thus, as in the case of cost estimates, it may be concluded that the robustness of ex-ante CBAs depends greatly on the robustness of traffic forecasts.

CBA as a Source of Bias in Itself?

It has been contended in the literature that, paradoxically, one of the main sources of bias and inaccuracy in transportation appraisal may be the CBA itself. For example, the Transport Planning Society in the United Kingdom has suggested that the strong reliance on NPV–cost ratios in appraisal and decision-making leads project promoters and their consultants to abuse the system by artificially boosting the values of positive elements in the CBA and downplaying the costs. This suggestion is in line with Oxford economist Bent Flyvbjerg's allegations that transportation planners routinely engage in strategic behavior and rent-seeking to justify their own projects or those of their clients (Flyvbjerg, 2009). However, the claims and allegations have not been proven by scholars, nor have they been supported by any empirical data. Moreover, not all countries require positive binding corporate rules (BCRs) for projects to be implemented, and the results from different studies vary with regard to forecast accuracy. Thus, there is insufficient evidence to accuse transportation planners in general of fraudulent behavior, as there is no statistical evidence to prove that CBA values are subject to tampering.

Improving the Robustness of CBAs Through Ex-Post Evaluations

Apart from the criticisms of CBAs being inappropriate tools for decision-making because they do not include all relevant factors worth considering in decision-making and some important impacts are not valued in monetary terms, there is criticism related to robustness, which the transportation literature has addressed to a lesser extent. The criticism is that CBAs are rarely conducted ex-post (i.e., at some point after a project has been implemented).

Ex-post evaluations, if conducted regularly, can improve the robustness of CBA as decision-making tool in the following ways: they can (1) provide input for the development of CBA techniques over time, (2) provide important lessons for CBA users who are looking for practical evidence regarding delivering transportation projects, (3) show results to policymakers who want to know whether schemes deliver planned benefits and whether transportation policy is as effective as intended, and (4) show communities whether their concerns are being addressed effectively.

Ex-post CBA evaluations are conducted by substituting ex-ante estimated values by ex-post actual values as far as data availability allows. Although there has been an increase in ex-post evaluations of transportation projects over the last 10–15 years, very few countries have standardized and mandatory frameworks for such analyses. Among the few countries that carry out annual ex-post CBA evaluations are the United Kingdom, Norway, France, and New Zealand. In the United Kingdom, Highways England carries out annual Post Opening Project Evaluation (POPE) 1 and 2 years after the opening of selected projects. France has “permanent observatories” that are established by law and used to collect data to facilitate a detailed evaluation of major schemes. Norway and New Zealand both conduct ex-post assessments of some of the impacts of a small sample of projects every year. In addition, the European Union regularly initiates ex-post studies of EU-funded projects. Other countries, including Sweden, carry out ex-post evaluations of individual projects from time to time (Nicolaisen and Driscoll, 2016).

The CBAs in all of the aforementioned countries are based on uncertainties to varying degrees. However, several Swedish studies have shown that CBA rankings are robust against uncertainties in input parameters and that even omitted demand due to land use effects have had a limited effect on project rankings. The uncertainties cause negligible losses of total net benefits, and project selections based on CBAs deliver far higher total benefits than projects for which selections are made at random (Börjesson et al., 2014).

Do CBAs Answer the Right Questions?

Regardless of the inaccuracies discussed in the preceding sections, the robustness and usefulness of a CBA will depend primarily on whether it is able to capture the policy aspirations of decision-makers. A number of studies have criticized CBA as an ex-ante appraisal tool because unacceptable environmental effects may have a very limited impact on a project’s NPV. Others have criticized the ethical foundations of CBA, in particular the lack of emphasis on equity and distributional effects. There may also be an intergenerational equity problem, due to the use of a discount rate, and there is no guarantee that a project with a positive NPV will be acceptable from a sustainability perspective.

In practice, decision-makers may have goals (both short term and long term) that may be at odds with the results of an economic appraisal. For example, in many CBA frameworks, the travel times of motorists are valued higher than the travel times of transit passengers. This may favor car-based strategies for urban areas instead of strategies based on improving options for transit, walking, and cycling. In other cases, reduced travel time through better access roads to cities may encourage deagglomeration. Better roads encourage people to buy larger and potentially cheaper houses farther away from the city. This leads to increases in traffic, which is valued as induced traffic in the CBA, but in practice the amount of time a motorist spends traveling may be unchanged while the effects feed into the economy through increased property prices. In many road projects time savings may benefit individuals, but offer little benefit to society. We need to recognize that not all transportation investments improve the economy, and not all projects meet local and national objectives, such as reducing peak-hour congestion and emissions. Thus, from a societal point of view, the economic impacts as measured by the CBA may be both positive and negative.

A CBA answers merely one of the questions that decision-makers may be interested in, namely the value for money generated by a scheme. The appraisal of projects should be based on a broad framework, which includes a strategic perspective that outlines the rationale for a project. The economic case, as measured by the CBA, is there to support the strategic case, and not to dictate decisions. The strategic case should act as a filter to prevent projects with impacts that are counter to current policy, even if they have a positive NPV. Thus, appraisal should be based on an analysis of multiple objectives and not just on monetized costs and benefits as measured by the CBA. Otherwise, CBA may not be regarded as useful or robust in solving the problems that decision-makers face.

The Robustness of CBA in a Future Perspective

Despite all of its flaws and weaknesses, CBA has been a useful tool for transportation agencies and decision-makers for many decades. It has aided in the selection of projects that improve the economic welfare of societies and it has helped to prevent economic waste. Despite its often-limited practical use, CBA has added transparency to planning and decision-making processes in which a wealth of detail can obscure the overall picture.

However, in a future that may look dramatically different from the past, the old ways of appraisal may no longer be fit for purpose. We have discussed changing objectives and the role of economic appraisal in a broader framework of project governance, but today we are also faced with changes and challenges that may leave planners with less solid ground on which to stand.

We live in a transitional age. Although vehicles have remained relatively unchanged for 50 years, the age of electric and autonomous vehicles is upon us. In Norway, the market share of electric vehicles as a proportion of all sold vehicles increased from just over 0% in 2010 to over 30% in 2018. In other countries, the change has been less significant, but there is no doubt that vehicle technologies are about to change dramatically and take on forms that we may not be able to foresee today.

New technologies and new behaviors are disrupting long-established patterns. Services such as Uber are breaking down the divide between vehicle ownership and the transportation industry. Connected and possibly autonomous vehicles allow us to utilize road space more efficiently. App-based services encourage new forms of mobility that may be difficult to predict. Additionally, attitudes to travel are changing. While traveling the world might have been seen a sign of success in the past, “flight shame” is set to become the buzzword of 2019 in Northern Europe. All of these new trends translate into a major challenge for transportation

appraisals. Accurate forecasting of outcomes is set to become even more challenging than in the past, and the answers give today may not be appropriate in the future. In an age of change, the risk of misallocation of resources through spending on projects or services that may prove irrelevant in the future increases considerably.

The answers to a more uncertain future should not be to abandon ex-ante appraisal and CBA altogether. Instead, we need to acknowledge that there may not be one correct solution to a problem, and that transportation planning needs to incorporate multiple scenarios and solutions. We also need to take a broad view of possible outcomes and aim policy toward the direction that is desirable for society.

Concluding Remarks

In this chapter, we have discussed the robustness of CBA with regard to its usefulness in decision-making, given uncertainties about crucial input parameters and uncertainties about future needs and priorities.

We have argued that the main purpose of CBA is to rank projects in a project portfolio or to select project alternatives, such as road alignment, in a given project. In this context, CBA is robust, as inevitable inaccuracies of costs and benefits are unlikely to alter project rankings. However, a range of studies has demonstrated a high degree of uncertainty regarding costs and traffic in transportation projects worldwide, and therefore there is potential for improvement in ex-ante estimates and methods. We have argued that ex-ante CBA should be combined with a framework for ex-post evaluation so that we can learn about actual project performance, and increase transparency and accountability.

Although widespread, the often-limited use of CBA results suggests that decision-makers may have other priorities than those that can be summarized in monetary terms. There is a need to recognize that CBA is merely one element in a framework for project governance and that the economic case for a project should be one element in a broad strategic appraisal.

Project uncertainty does affect not only individual projects, but also the context in which projects are selected and implemented. In a world of changing needs, priorities, and technologies, we must recognize that CBA may not represent all the answers for future scenarios.

Introduction

The gross domestic product (GDP) impact of transport investment has a strong resonance with policy. Investment in transport infrastructure is seen as one of the ways of growing economies and reducing spatial disparities. Economic growth is an objective of transport investment by international agencies such as the World Bank, the Asian Development Bank, as well as by the European Commission (EC) and national governments. The EC's Cohesion Fund for 2014–2020 is €63.4 billion and has the objective of reducing spatial disparities in the EU and will either finance transport or renewable energy-oriented projects. Economic growth, particularly in the north thereby reducing spatial disparities, is a key objective of the High Speed 2 (HS2) and the Northern Powerhouse Rail high-speed lines in England.

When thinking about the GDP effects of such transport investment at a regional or country level, we need to consider how transport investments feed into the regional and national economies. In this paper, we therefore take the reader through the key macroeconomic mechanisms starting from neoclassical theory through to the more modern New Economic Geography (NEG) theory in Sections “Neoclassical Approaches,” “Endogenous Growth and New Economic Geography,” and “Transport-Economy Frictions.” In particular, we draw out the implications of transport investment on productivity growth and the displacement of economic activity. In Section “Evidence of Transport Investment's Impact on the Economy,” we then present and discuss the evidence on how transport investment has effected the economy historically. We draw out variations by estimation approach, industry, mode, country, region, and income levels, and examine whether historical timing is of any relevance, before concluding in Section “Conclusions.”

Neoclassical Approaches

The Production Function and the Solow–Swann Model of Regional Growth

Classical approaches to understanding economic growth, whilst ultimately insufficient to give us a full understanding of the role of transport in growing an economy, are very enlightening as they describe some of the key building blocks which more complete theories utilize. The starting point invariably is a production function, which relates aggregate output (Q), to inputs of labor (L) and capital (K):

$$Q = f(L, K) \quad (1)$$

Imposing a Cobb–Douglas form on this function gives us an equation of the form:

$$Q = AL^\alpha K^\beta \quad (2)$$

The key implication of this model is that transport infrastructure investment gives a one-off shift in productivity. This is because at time t_1^* growth returns to the long-run rate of growth. The second important implication is that the productivity growth occurs in two stages: an immediate jump in productivity followed by a gradual, but diminishing, rate of growth. Over this period of time growth exceeds the long-run rate of growth in the economy (here depicted by the rate x).

From a policy perspective the time interval between t_1 and t_1^* is important. A short time interval would mean that it would be possible to focus exclusively on the level of productivity and output once the economy has returned to its long-run rate of growth, whilst a long interval would mean it is necessary to understand the dynamics of this change. Evidence suggests this adjustment period is very long with the gap to steady state narrowing by between 1.5% and 3% per year (Barro and Sala-i-Martin, 2004). This implies that 50% of the gap is narrowed (half life) between 22 and 45 years, and 75% of gap is closed between 45 and 91 years. Ultimately therefore, despite being a one-off shift, the effects of a transport investment on regional growth is likely to be felt over a very long time.

This model also informs us that if the performance of the transport networks worsens over time, for example, for reasons of say demographic change, technological change, or income growth leading to higher levels of congestion, then the locational efficiency of a region (the A term) will decrease. This will result in a contraction of the production function. Some transport investment may therefore be required to maintain existing productivity levels if transport networks are expected to become more congested in the future.

Gains From Trade and Comparative Advantage

Transport infrastructure investment also facilitates trade between regions and between countries. Davide Ricardo in the early 19th century was the first to describe the gains that can be made from trading. He showed that if transport costs (and other costs to trade) fall sufficiently to permit trading, then countries will specialize in the industry for which they have comparative advantage. In his example Portugal was more efficient at producing both wine and cloth than England. It therefore has absolute advantage over England. Its comparative advantage though is in producing wine, as it uses less inputs to produce wine than it does to produce cloth. In his example England's comparative advantage was in producing cloth, rather than wine—as England used less inputs to produce a unit of cloth than it did to produce a unit of wine. He then showed that if trade costs, of which transport costs are part, fall sufficiently to allow trade between the countries then both countries will specialize in the industry in which they hold comparative advantage. This would be wine for Portugal and cloth for England. In doing so, more cloth and wine would be produced for the same inputs of labor. That is by specializing in the industry of comparative advantage and trading: productivity increases, incomes increase, and society is better off. This is also known as gains from trade.

Ricardo's model is very simple and it requires that labor and capital will not migrate between countries or regions, and that different regions or countries hold comparative advantage in different industries. Nonetheless, the model is illustrative of the productivity benefits we gain from specializing in the tasks or industries we are best at. However, by specializing there is a need to trade otherwise we cannot produce all the commodities our region, city, and locality require. Transport is therefore part of this story of specialization. How important this ability to trade is to our overall productivity is a good question that is difficult to answer. We can draw to an extent off the situation which Gaza found itself in during the blockade of 2007–10 which is estimated to have reduced Gaza's productivity by 23% (Etkes and Zimring, 2015).

We can therefore see that transport investment, as well as directly boosting productivity through an outward shift in the production function, can permit increases in productivity through specialization and increased interregional trade.

Migration and Displacement

Labor and capital also migrate between countries and regions. In a simple neoclassical model, workers migrate to maximize their return to providing labor, and owners of capital invest in other regions to maximize their return on investment. This migration of both labor and capital between regions leads to an equalization in both returns on capital and labor between regions. This is because the return on labor decreases in the region it migrates to, as labor supply in the recipient region increases. Simultaneously, the return on labor increases in the donor region as labor supply contracts. The movement of labor between the regions eventually leads to an equalization of wage rates between regions. The same is true for capital. If we introduce migration into the Solow–Swann model presented earlier it can be shown that the speed of convergence to the steady state speeds up. That is, the economy will grow more quickly, up until the point that growth reverts to the rate at which the population grows.

In reality of course there are many barriers to full factor mobility, which prevent rates of return equalizing between regions. There are distance, information, and money costs. There are different risks between regions, and full factor mobility is not usually possible (e.g., different segments of the labor market are more mobile than others and some economic activities are fixed in location). Notwithstanding these criticisms, this simple model is useful as it illustrates how a productivity shock, such as a transport investment, destabilizes the equilibrium. Following a productivity enhancing transport investment, mobile factors of production will shift to the more productive region expanding the supply of capital and labor in this region, and reducing the supply in the donor regions. At the new equilibrium the rates of return on capital and labor will be higher in all affected regions than before the transport investment. Furthermore, activity will have been displaced to the region that received the productivity shock. This displacement of economic activity between regions by transport investment is a key economic response, and arguably gives rise to the most notable change in economic output (GDP) in the vicinity of the transport investment.

Endogenous Growth and New Economic Geography

An Introduction to Endogenous Growth and New Economic Geography

A key critique of neoclassical growth theories is their inability to adequately explain, within the model, why disparities remain between regions and countries. Long-run growth in developed economies has been sustained over many decades, and developing economies have not “caught up.” Within countries, some regions “lag” behind. Theories on endogenous growth and the field of NEG offer insights here, and give a more nuanced view as to the role of transport investment in boosting economic performance.

Endogenous growth emphasizes the role of human capital as a source of long-run economic growth through the creation and diffusion of knowledge. Education, research and development, and new ways of working, both within business and as a consequence of the institutional setting, all form mechanisms by which long-run growth can occur.

NEG links agglomeration economies, internal economies of scale, and transport costs as sources of imperfect competition. This imperfect competition then permits the spatial variation in economic performance between regions that neoclassical models cannot predict. NEG emphasizes that there exist centripetal forces that will centralize economic activity (market size effects, thick markets, and knowledge spillovers and other pure external economies), and centrifugal forces that will disperse economic activity (immobile factors, land rents, congestion, and other pure diseconomies). A policy shock, such as a transport investment, will then disturb the existing balance and the relative strengths of the different centripetal and centrifugal economic forces will determine whether economic activity will centralize or disperse.

Later we explore the implications of this on the economic performance in the context of an intraregional (and urban) transport investment, an interregional (or intercity) transport investment, and the implication of transport for long-run economic growth.

Intracity Transport Investment: Economic Growth and Displacement

As mentioned earlier and discussed elsewhere in this volume there are external benefits to clustering—agglomeration economies. An intracity transport investment would be expected to raise productivity by the mechanisms outlined earlier, and in so doing will displace economic activity to the city. This will raise city productivity further, and in so doing will induce a circular-and-cumulative causation process that continues to displace economic activity to the city until a new equilibrium is reached. The key point from a transport investment is that the presence of agglomeration economies can therefore increase the productivity of a city and the effect of regional displacement beyond that expected by the simple neoclassical model.

Interregional Transport Investment: Economic Growth and Displacement

Possibly the largest contribution of NEG with respect to the economic impact of transport investment is with respect to interregional or intercity transport investment. If economic activity is mobile then the choice of which region to locate production can be shown to vary with interregional transport costs. With high transport costs production will occur in every region; with medium transport costs production will centralize to those with the largest markets, and with low transport costs production will disperse to regions with low factor costs. That is, as transport costs fall spatial inequalities between regions increase, but as they continue to fall this trend will reverse and spatial inequalities between regions start to diminish. This is the bell-shaped curve of NEG.

Noble Laureate Paul Krugman illustrated this process with a simple two-region model. In this model there are two regions: the core and the periphery. The core is larger than the periphery, whilst the periphery has lower factor costs (land rents, wages, etc.). There are no transport costs within a region, but there are transport costs between the regions. Firms also benefit from internal economies of scale in production. Populating this model with some hypothetical data (Table 1) Krugman shows that with high transport costs firms will locate a factory in both regions and there will be no trade between regions. This is because total costs of production of a single large factory in the Core is 13 units ($=10 + 3$), a single large factory in the periphery is 16 units ($=8 + 8$), whilst having two smaller factories one in each region is lowest at 12 ($=12 + 0$). With medium shipping costs it becomes cost effective to close one factory and expand output at the other factory. The factory at which production centralizes is located in the largest home market to minimize transport costs—which is the Core in this scenario. Under medium shipping costs total costs of production in the Core is 11.5 units. That is, a lowering of transport costs leads to a trade between regions and a centralization of economic activity to the largest regions. A further reduction in interregional transport costs will eventually lead to production locating in the regions

Table 1 Economies of scale exist in production (either internal or external)

<i>Production in</i>	<i>Production costs</i>	<i>High shipping costs</i>	<i>Medium shipping costs</i>	<i>Low shipping costs</i>
Core	10	3	1.5	0
Periphery	8	8	4	0
Both	12	0	0	0

Source: Krugman (1991).

with lowest factor costs—which in this model is the Periphery. Here, with low shipping costs the total costs of production in the Periphery is 8 units ($=8 + 0$).

Reorganization effects (i.e., displacement) at a regional level in response to the transport cost reductions are therefore substantial, and in this hypothetical example dwarf the productivity gains. The key contribution relative to the neoclassical model is that economic activity may locate to either end of the interregional transport link depending on the existing level of development in the country. Arguably therefore investment in interregional transport links in developed countries with mature transport networks and relatively low transport costs will lead to a dispersion of economic activity. In contrast transport investment in developing countries with immature transport networks with associated high transport costs will lead to a centralization of economic activity.

Transport Investment and Long-Run Growth

In the neoclassical model transport investment gives a one-off productivity increase (with associated increase in economic output), albeit this is likely to take several generations to fully materialize. After this period, growth returns to the pre-intervention long-run growth rate. Endogenous growth theory emphasizes that the source of long-run growth is through the creation and diffusion of knowledge. Obviously transport investment does not directly influence this source of growth, but it may indirectly do so by strengthening agglomerations. This is because one of the sources of agglomeration economies is learning effects relating to the creation, diffusion, and accumulation of knowledge. Transport investments, by indirectly strengthening learning effects within a regional economy, may therefore affect the long-run rate of growth. The original NEG models were primarily concerned with the spatial organization of economic activity, but in more recent NEG models spatial organization and growth are jointly determined. These theoretical models suggest changes in location of economic activity are associated with faster growth in all regions. These theoretical models are, however, relatively recent, and more research on them and their empirics is needed.

Transport-Economy Frictions

The preceding discussions have been on the presumption that factor markets are not distorted and will clear. If there exist structural weaknesses in the economy that prevent firms accessing a labor force with appropriate skills, land suitable for development, or capital to finance investment, then the growth and reorganization effects described may not occur. Furthermore, in a developed country with a mature transport network, it is viewed that transport is a complement to more important factors of economic growth—the most important of which is an available workforce (Bannister and Berechman, 2001). This is a cautionary note as transport's ability to stimulate the economies of lagging regions or countries will be limited if they there are structural weaknesses present in those regions/countries. As an intermediate good, the pass-through mechanism needs to be working well for transport to influence economic growth and boost GDP.

Evidence of Transport Investment's Impact on the Economy

The evidence of transport's impact on the economy is largely from studies focused on estimation of Cobb–Douglas production functions based on aggregate country or state level data: these yield an elasticity capturing the sensitivity of output to changes in the stock of public capital stock, of which transport infrastructure is a key component. Referring back to Eq. (3), such studies cannot distinguish between effects through capital stock K and effects through transport services influencing the A term: they both involve estimating coefficients on public capital.

We see in national and regional economic data that there is a clear correlation between output measures (GDP) and transport investment levels. However, in understanding the evidence a key concern is to identify causality, that is, does transport actually drive economic growth or is it vice versa or is there no direct relationship at all? There are a host of studies in the literature to draw on here. There is a separate paper in this Encyclopedia that addresses the issue of causal identification and we do not therefore discuss it here, beyond saying that inadequate methods to address causality can result in overly large estimates of the impact of transport investment on economic output.

An early key study was conducted by David Aschauer (Aschauer, 1989) who sought to explain the impact of public sector investments on US output using an annual time series dataset of aggregate public capital stock and total factor productivity measures from 1949 to 1985. His work identified a strong relationship between real output and the stock of core infrastructure (including highways, mass transit, airports but also utilities) during this time period which was quantified in an output elasticity of 0.24; that is, an increase in the stock of core infrastructure of 10% would lead to an increase in real output of 2.3% ($=1.1^{0.24}$). From this evidence Aschauer attributed the decline in productivity in the United States since the 1970s to underinvestment in public infrastructure.

Whilst Aschauer's work offered compelling evidence, there were a number of questionable aspects that prompted a host of subsequent studies using aggregate country or state level data and more sophisticated estimation techniques. Key findings of these studies are best summarized through consideration of meta-analysis study findings (Melo et al., 2013; Holmgren and Merkel, 2017).

Meta-analysis studies in this area seek to explain variation between many separate studies that examine the relationship between transport investment and the economy in order to understand whether there is consistent evidence of such a relationship underpinning the studies.

One such study was conducted in 2013 by Patricia Melo, Daniel Graham, and Ruben Brage-Ardao looking at a dataset of 33 studies that focused on the output elasticity of transport. The mean value of the output elasticity from these studies was 0.06 with a median of 0.016: substantially lower than Aschauer's estimates and with a considerable variation in the values as captured by a high standard deviation. They used the meta-analysis to capture the effect of various study characteristics on the resultant estimates with the aim of explaining the wide-ranging results from the literature and offering guidance to policy-makers on returns to transport investment.

Whilst some of these constituent studies were based on time series approaches, others included panel data analysis using repeated observations over time on spatial units (e.g., US states). Analysis of panel data allows studies to control for estimation bias arising from unobserved time invariant heterogeneity. Other examined sources of variation included mode, sector, country, spatial scale, income level, and time frame.

Estimates such as Aschauer's, based on pure time series, yielded higher values than subsequent studies: this may be partly due to spurious associations between output and infrastructure stock which both grow over time but may not be causally linked. Subsequent studies (Holtz-Eakin, 1994) that controlled for unobserved heterogeneity through panel data approaches yielded lower elasticity values. This may be because more prosperous areas are likely to spend more on public capital leading to a positive correlation between area-specific effects and public capital: if not controlled for this will manifest itself in a higher coefficient on transport infrastructure investment. Other studies investigate potential bias in the elasticity estimate by employing methods which correct sources of reverse causality: governments may choose to invest more in growing regions to promote further growth or conversely to invest more in lagging regions to harmonize economic fortunes across regions. The idea here is to find a proxy for transport infrastructure purged of endogeneity with the output measure—often based on long lags of infrastructure or related measures that cannot be linked to current levels of output (Duranton and Turner, 2012). Melo and her coauthors find that controlling for this reverse causality yields higher elasticity measures suggesting transport investment on average across their sample is targeting toward lagging regions. More urbanized areas are associated with higher levels of transport infrastructure and output and if a measure of urbanization is not included Melo and her coauthors' findings suggest it can lead to upward bias in output elasticities. Conversely they find studies that do not control for congestion yield lower estimates and this may hamper productivity benefits from agglomeration.

In terms of other sources of variation, there are higher elasticities for manufacturing industries relative to other sectors, reflecting that these sectors are more transport intensive: Melo and her coauthors report average values of 0.082 for manufacturing sectors. They also find higher elasticities are evident for road-based infrastructure (0.088) compared to other modes (e.g., rail and air are 0.037 and 0.027, respectively), although this may reflect the higher stock of roads than other modes, that is, a 10% increase in road infrastructure is a larger absolute increase than a 10% increase in rail infrastructure. There are also higher values for the US-based studies possibly reflecting the higher use of roads in the United States.

As an aside it is useful to understand what these elasticities might mean in terms of rates of return on investments. For example, Grice (2016) in recent work on national accounting measures estimates UK transport stock to be worth £569 billion in 2014. If we take an example of a £1 billion transport investment: this implies an increase of 0.18% in the infrastructure stock. An elasticity of 0.06 applied to this proportional increase in the infrastructure stock amounts to an increase in GDP of 0.01%. Applied to a real level of GDP of around £2 trillion this would give a GDP increase of 211 million per year, which is a rate of return of 21.1%. That is the infrastructure pays for itself within 5 years.

The evidence is more mixed for non-European studies. However, Canning and Bennathan (2001) in a report for the World Bank, estimate output elasticities for paved roads at 0.05 for countries in the lowest income quartile and 0.04 for countries in the highest income quartile compared to a median value of 0.09. This contrasts with the theoretical models presented earlier, which suggested that poorer countries should experience the highest returns. However, in some poorer countries productivity is likely to be constrained by low levels of human capital and disparate and disconnected infrastructure networks thus creating frictions that prevent the economy exploiting the improved infrastructure. In richer countries diminishing returns have set in terms of benefits from expanding networks beyond a critical level of capacity (such as the US interstate highway network), which is why we expect and see low elasticities there. Middle-income countries may sustain higher elasticities due to gains from trade and higher levels of other inputs such as physical and human capital (linking to endogenous growth theory).

Studies using national data yield higher estimates; these studies are more likely to pick up spillover effects than more regionally disaggregate ones. In terms of time there are higher elasticities in the long run (more than 5 years) than the short run (less than 5 years). In the time frames observed, such studies do not tell us whether we are adjusting back to a steady state or moving to a new long-run rate of growth (endogenous growth). Clearly it is difficult to make comparisons against the theory when the adjustments require much longer time series than data currently permits.

Their mean value of elasticity of 0.06 in Melo's study, whilst considerably lower than Aschauer's, is itself thus possibly an overestimate given the older studies do not address sources of upward bias. Another similar meta-analysis exercise found that studies centered around 1965 or earlier have significantly higher estimates than more recent ones (Holmgren and Merkel, 2017). Further, earlier studies may be based on older US data where large network effect benefits from the development of the interstate highway network in the 1950s and 1960s connecting previously isolated states, were a one-off benefit.

Conclusions

There are strong theoretical reasons to believe that transport will affect the size of an economy. It can shift the production function outwards by affecting the stock of capital in the economy and by making the economy more efficient. This is a one-off shift, albeit taking several generations to materialize, and a change in long-run growth will only occur if transport investment can change the rate of knowledge creation and diffusion—the source of long-run economic growth. One potential avenue it may do this is by affecting the effective size of agglomerations. Transport investment is a destabilizing force, as by changing transport costs it changes the balance between regions and countries. This can lead to productivity gains from agglomeration and specialization, but is also likely to lead to reorganization and displacement effects. Whether economic activity centralizes or disperses is a function not only of existing transport costs, but also of the relative strengths of centrifugal and centripetal economic forces.

The empirical evidence backs up the theory to the extent that it clearly shows a linkage between output and transport investment as captured by positive output elasticities for changes in the stock of transport infrastructure. There is no “one-size-fits-all” elasticity, with notable variations by industry, region, spatial scope, and income levels. More recent work tends to yield lower elasticities and suggests that early literature presented overestimates due to issues with data and estimation approaches and also due to the one-off gains associated with development of networks. The datasets are not long enough to make clearer linkages with the types of growth that is enabled and this is an area where more evidence is needed, although other empirical studies on agglomeration impacts may provide more insight as to the extent to which such growth may be endogenous.

Introduction

Herbert Mohring (1928–2012) was one of the most influential economists in the field of transportation economics. He was one of the first economists to study land values and its relationship with transportation costs in the monocentric model. He is also well known for his contribution to the theory of cost recovery for highway construction, especially for the joint work with Mitchell Harwitz that studied the conditions under which road provision is exactly financed with optimal road tolls. He has also contributed to the urban transportation policy analysis by studying the efficiency of dedicating road capacity exclusively to buses and comparing its benefits with those from welfare maximizing pricing policies. The present article discusses his contribution on economies of scale and subsidization in public transportation.

The Mohring Effect is the result that an increase in the demand for public transportation induces a decrease in the waiting time costs for all users when it is dealt with an increase in the frequency of the services. Its origin is in the article titled “Optimization and Scale Economies in Urban Bus Transportation” published in the *American Economic Review* in 1972. The term Mohring Effect has also been used in a broader way and has included other positive indirect effects of increased demand, such as reductions in access time costs from increased route density. When the average costs, including those of the users, decrease with the demand, the social welfare maximizing public transportation fare does not cover operating costs. Therefore, the Mohring Effect, which is in a way analogous to a positive externality, is the most important argument from an economic efficiency standpoint for public transport subsidization. The other arguments for subsidization, such as reductions of car travel externalities and distributional concerns, may be better addressed with instruments directly targeted at those objectives.

Recent estimations using data from large and congested cities have shown that the Mohring Effect is substantial and that it plays a key role in justifying the presence of public transport subsidization. It has also been shown that the Mohring Effect is more significant for buses than rail and subways and that is more significant for off-peak periods than for peak periods. The intuition behind these results is that the Mohring Effect is stronger for low frequencies that imply significant waiting times, and frequencies are higher in peak periods and urban rail services.

Section “The Mohring Effect in a Simple Framework” of this article discusses a simplified version of Mohring’s framework that illustrates the nature of the Mohring Effect and why it is an efficiency argument for subsidizing public transportation. Section “The Mohring Effect in the Original Framework” summarizes Mohring’s original model and his numerical results. Section “Empirical Evidence on the Mohring Effect” reviews the recent empirical evidence on the size of Mohring Effect and estimations on how much of current and optimal subsidies in some cities are due to the Mohring Effect. It also discusses more generally under which conditions the effect should be strong. Finally, Section “Conclusions” concludes providing a summary and some present challenges related to this topic.

The Mohring Effect in a Simple Framework

Mohring, in his pioneer work published in 1972, started the literature on the microeconomics of urban bus transportation. The aim of his paper, which gave rise to what is now known as the Mohring Effect, was to study scale economies in the provision of public transportation. In other words, [Mohring \(1972\)](#) studied the short- and long-run cost functions to characterize the nature of increasing returns to scale in bus operations and thus to assess the nature of the subsidy required if marginal cost pricing is in place.

Transportation differs from the classic analysis of pricing because consumers (i.e., travelers) play a producing role by providing their own time as a resource for production. In using bus services, they must supply their time, distributed at least into access

(walking), waiting, and in-vehicle time. These time costs borne by the travelers can be substantial: estimates for the value of time for commute trips are typically around 50% of the wage rate, and the values of waiting and access time are 2 or 3 times larger.

Mohring's model considers a bus corridor or line, where the demand is spatially distributed. As the focus is on costs, demand is treated parametrically. He examines four components of costs: (1) bus company operating costs, (2) passengers' walking time costs, (3) passengers' waiting time costs, and (4) passengers' in-vehicle time costs. The sum of these components is sometimes called in the literature as the total value of resources consumed.

The variables that the bus agency optimizes are the frequency of the buses and the spacing of bus stops. A key assumption in the model, which is rooted in transportation engineering, is that the waiting time is a function of the headway between buses. Therefore, as the headway is the inverse of the frequency, the average waiting time costs are inversely related to the frequency of buses.

A primary result of the analysis, inspired in William Vickrey's previous work, is that, when bus speed is constant, the frequency that minimizes the expenditure is proportional to the square root of the demand for bus services. This has become a result commonly known as the "square root formula" for the optimal frequency of bus services, and it has been extended in various directions and found to be fairly robust (Jara-Díaz and Gschwender, 2003).

In his paper, Mohring modeled in a detailed fashion the realized bus speed as a function of frequency, the distance between bus stops, and free-flow speed. However, the Mohring Effect can be understood without this complexity. This section considers that bus speed is constant and therefore the square root formula is valid, and it assumes for simplicity that the number of bus stops as well as their location are fixed. The following section deals with more complex models.

The implications behind the square root formula are intuitive. As the average waiting time is inversely related to the frequency, and the frequency is proportional to the square root of the demand, the average waiting cost decreases with total demand. This result is the essence of the Mohring Effect: an increase in demand reduces waiting costs for all passengers, as it should be dealt with an increase in frequency.

The Mohring Effect is, therefore, one source of increasing returns to scale in bus operations because waiting costs grow less than proportionally with demand. In other words, due to the Mohring Effect, the marginal cost could be less than the average cost and the welfare maximizing bus fare does not cover operating costs. As a consequence, the Mohring Effect is a driving force of the efficiency of public transport subsidization.

The strength of the Mohring Effect and, therefore, to what extent it justifies public transport subsidization depends mainly on the frequency implied by the level of demand. Consider a simple example of a bus route with low demand for which the optimal frequency is two buses per hour. Assume for simplicity that the average waiting time is half the headway so that in this example is 15 min. If demand is doubled and the optimal frequency follows the square root formula, it increases by a factor of the square root of 2, which yields a new frequency of approximately three buses per hour. The increase in frequency from two to three buses per hour reduces the average waiting time for all passengers from 15 min to 10 min. While this can be substantial, as demand grows and the frequency is higher, the effect becomes smaller. For a frequency of 30 buses per hour, the average waiting time is 1 min, and the potential decrease in waiting costs is limited. Naturally, the real effect is complex as more interrelationships come into play. We now turn to discuss some of them.

The Mohring Effect in the Original Framework

As explained in the previous section, Mohring's model included bus company operating costs and passengers' walking, waiting, and in-vehicle time costs. The previous section assumes that buses travel at a constant speed for the ease of exposition, but, in Mohring's model, the speed that buses achieve is endogenous, and the analysis is more detailed. We summarize the main features of the model and his numerical results.

First, in the model, the speed of a bus depends on the number of passengers that board and alight each bus along the route and, therefore, it depends on the number of passengers and the frequency. Furthermore, the time spent in starting and stopping at the bus stops is modeled together with a probability of buses not stopping at all bus stops.

Second, Mohring studies two types of spatial distributions of demand. The "steady state" route in which demand is uniformly distributed along the bus line, and the "feeder" route in which the same average number of people per hour board buses but they all alight at the end of the route. For both travel demand patterns, the number of equidistant bus stops per mile is an optimization variable.

As a result of the complexity of the interaction between these features of the model, it is not possible to obtain closed-form expressions for the frequency and spacing of bus stops. Nevertheless, it is clear that, in contrast to the simplified version of the previous section, an increase in the bus frequency decreases both waiting and in-vehicle time. It also increases bus-operating expenditures but less than proportionally as the travel times are reduced. Finally, increasing the number of bus stops increases in-vehicle time for users and operating costs, but reduces walking costs.

To shed light on the degree of scale economies and the size of the optimal subsidy for urban buses, Mohring performed numerical analyses based on data that reflect approximately the Minneapolis–Saint Paul metropolitan area. The results are intended to cast light into the magnitude of optimal subsidies if the effects of bus pricing on highway congestion and the marginal cost of public funds are ignored.

The numerical analysis performed by Mohring is detailed, but the result that arguably better conveys the conclusion is as follows. For conditions that reflected the situation at the time in the Minneapolis–Saint Paul metropolitan area, results are that the weighted

average gap between long-run marginal costs and average costs is 57% of the bus company operating costs. Therefore, the optimal subsidy at those conditions is large and justified by the reduction in user time costs of increased frequency.

The combination of the theoretical and numerical analysis summarized earlier gave rise to the Mohring Effect, which, in a broad sense, is the result that as demand increases the average user costs decrease if the public transport supply responds optimally. This could be due to increases in frequency that lead to a reduction in waiting time and in-vehicle time due to lower boarding and alighting time. It could also be due to increases in bus route density, which leads to decreased access time. The Mohring Effect, thus, is a source of the presence of economies of scale in public transport provision and one of the main efficiency arguments for subsidizing public transport.

Empirical Evidence on the Mohring Effect

The vast majority of the empirical literature on public transportation pricing focuses on the optimality of public transport subsidization (Proost and Van Dender, 2008; Basso and Silva, 2014; Börjesson et al., 2017). In doing so, the studies have commonly estimated an aggregation of all the effects that could give rise to subsidization, and little can be said about specific effects. For example, the size of the optimal subsidy is a function of the strength of the Mohring Effect but is also determined by the degree of scale economies of the bus company operation. The subsidy also heavily depends on the unpriced externalities in urban travel. If car travel is not priced in a welfare maximizing way, lowering the public transport fare may decrease car usage and the unpriced negative externalities such as road congestion and pollution. This reduction potentially implies the need for higher subsidies. Finally, there could be negative externalities from bus travel as well, such as crowding, pollution, and congestion that could make the subsidies not efficient.

The primary empirical evidence about the size of the Mohring Effect and its role in the efficiency of public transport subsidization is a study with data from Washington, Los Angeles, and London by Parry and Small (2009). The study considers most of the relevant features that need to be taken into account in determining the efficiency of public transport subsidies. It includes several modes for traveling, demand substitution across modes and times of day, transit supply that is responsive to changes in ridership, negative externalities from motor vehicles (congestion, pollution, and accident), in-vehicle crowding in public transport, and transit-user wait and access costs. Importantly, the transit agency can adjust the route density, service frequency, vehicle size, and load factor.

The available estimations are not exactly the size of the Mohring Effect, but the marginal welfare gain of increasing the subsidy that is due to the Mohring Effect. More precisely, it is the marginal benefit minus the marginal cost of increasing the frequency and the route density in welfare maximizing fashion as a response to the increased demand that is a consequence of the fare reduction. The marginal benefit arises from the reduction in wait costs from increased service frequency and the reduction in access costs from increased route density. The marginal cost is from increased agency supply costs from increased vehicle size and the increase in passengers' crowding costs from higher load factors. Therefore, while the estimations are not the Mohring Effect per se, they are a relevant measure of how important it is in shaping the optimal pricing policy.

At the baseline situation of the study, which already had subsidies between 50% and 80%, the size of the Mohring Effect is significant. For peak operations, the marginal welfare gains due to the Mohring Effect from increasing the subsidy in 1 cent per mile in peak periods are 0.34 cents per mile in Washington, 0.29 in Los Angeles, and 0.19 in London. In off-peak periods, where frequencies are lower, the gains due to the Mohring Effect are substantially larger: 2.00 cents per mile in Washington, 1.73 in Los Angeles, and 1.74 in London. For rail, the marginal welfare gains due to the Mohring Effect are smaller and vary between 15% and 50% of the gains estimated for buses. The only exception in the study is peak-rail in London, in which higher costs fully offset the benefits due to the Mohring Effect. This is most likely because London's subway is already very frequent, crowded, and its network of lines is dense.

Parry and Small (2009) also estimate what the optimal subsidy would be and what percentage is due to the Mohring Effect. For off-peak bus services, the optimal subsidy is above 90% of operating costs for the three cities and the proportion of the optimal subsidy that is due to the Mohring Effect is between 55% and 61%. For peak bus services, the results are case specific. For London, the optimal subsidy is above 90% of the operating costs, and only 15% of that subsidy is due to the Mohring Effect. For Los Angeles, the optimal subsidy is 74%, and the proportion due to the Mohring Effect is 22%, while in Washington it is 46% and the proportion is also 46%. For rail services, the optimal subsidy in the three cities is substantial (above 78%) in all periods, but the share due to the Mohring Effect is lower. In peak periods the Mohring Effect is responsible for 0%–10% of the subsidy and for 21%–41% in off-peak periods.

In summary, the recent empirical estimations confirm Mohring's early findings that increased demand for public transportation that is met with an optimal adjustment of supply leads to a substantial reduction in user costs. This result, which is the broad definition of the Mohring Effect, justifies subsidization on efficiency grounds at least before taking into account the distortions that would be introduced in the process of raising public funds for subsidies.

Conclusions

This article argues that the concise definition of the Mohring Effect is the result that an increase in the demand for public transportation induces a decrease in the waiting time costs for all users when it is dealt with an increase in the frequency of the

services. This article provides an overview of a simple framework to understand the Mohring Effect and of the original framework developed by Mohring. This article also reviews the recent empirical estimations of the size and relevance of the effect.

The Mohring Effect can be understood in a general fashion as the result that, as the demand for public transportation increases and the public transport supply responds optimally, the average user costs decrease. This could be due to an increased frequency that leads to a reduction in average waiting times, to increased route density that leads to reduced average walking times, and route structure changes that lead to lower transfer costs, among others.

Recent estimations of the Mohring Effect in congested cities of developed countries show that it is an important driving force of the efficiency of public transportation subsidization. While results are convincing, the evidence is still scant. A natural avenue for future research is to estimate the Mohring Effect in different situations and to assess empirically to what extent it is strong enough to justify public transport subsidization.

The present article has focused on the cost-side of the problem and has not dealt with the private, profit-maximizing, provision of public transport. There has been recently a debate in the literature about whether the Mohring Effect justifies subsidization when a monopoly firm supplies the service. The answer seems to depend on the assumptions on public transportation demand, user cost heterogeneity, and operating cost functions (see [Gómez-Lobo, 2014](#), for a synthesis). Studying the relationship among the Mohring Effect, the strategic interactions between public transport providers, the regulatory framework, and the need for subsidization seems a natural place for further research.

Introduction

Public transportation is an indispensable component of the multimodal transportation system, especially in the urban environment. This article introduces public transportation fare and subsidy from the lens of optimization. The analysis is limited to traditional public transportation services, which are characterized by shared vehicles, fixed routes, and predetermined timetables. Depending on the vehicle used, there are different forms of public transport, such as bus transit, rail transit, ferry, and even airline services.

Public transportation systems across the world differ significantly in ownership, market share, fare scheme, subsidy availability, and regulatory policy. In the United States, the majority of public transport services is provided by governments at all levels (local, state and federal) with the objective of providing a viable travel alternative to driving. The market share of public transit is minimal (e.g., 5%) at the national level in the United States, while the share can be over 50% in major metropolitan areas, such as New York City (NYC). In the United States, due to the relatively low public transit demand, the farebox recovery ratio (i.e., fare revenues divided by total operating expenses) is usually quite low. For instance, the Metropolitan Transportation Authority in NYC has an agency-wide farebox recovery ratio of 35.5% in 2018 (MTA, 2018). By contrast, in major cities in East Asia, such as Hong Kong, public transit services can be operated profitably by private operators, thanks to relatively high population densities, large shares of commuting by public transit, and the innovative “rail plus property” business model (Leong, 2016). European transit systems fall between Asia and North America, facing various degrees of financial difficulty to achieve the break-even point, similar to the United States.

In the public transit pricing and subsidization literature, various demand functions, optimization objectives, constraints, and other modeling elements are used to reflect the regional characteristics. This article proceeds as follows: The second section discusses fare schemes, optimization methods for determining fares, and how optimal fares are affected by various economic and social factors; the third section analyzes whether external subsidies are needed, how such subsidies should be optimized, and how welfare losses due to subsidization can be mitigated; and the last section concludes this article with a summary.

Public Transit Pricing

In most public transport systems, passengers need to purchase tickets to take public transit. Although some transit services (such as inner-city circulators) are provided for free, it is rare to provide free transit services throughout a network or city. Nonetheless, there are examples of zero-fare public transit in the world: in Estonia's capital Tallinn public transport is free to all registered residents (Gray, 2018). When there are no fare revenues, funds from other sources such as government taxes or advertising are required to cover the transit operating expenses.

In most public transit systems across the world, the flat fare is adopted, partially because it is easy to communicate and simple to collect. If the same price is charged regardless of the travel time period, distance, direction, and quality of service (e.g., local vs. express bus), the actual operating cost of providing a passenger trip is not reflected. Intuitively, it should cost more to carry a rider over a larger distance during peak hours. To account for the operating cost differences, differentiated fares can be adopted based on travel distance or time of day. Cervero (1981) evaluate fairness in public transit pricing by comparing flat and differentiated fares. In Cervero (1981), it is defined to be fair if the costs of providing transit services are equitably and efficiently distributed among all transit users, despite other definitions of fairness in the economics literature. Based on data from three transit agencies in California, this paper finds long-haul riders are heavily crosssubsidized by those short-haul, off-peak transit users. It is suggested that differentiated fares should replace flat fares due to their advantages in improving equities among transit users. However, several obstacles to differentiated pricing especially political acceptability and institutional barriers are discussed. Cervero (1986) focuses on differentiated pricing by time-of-day involving transit agencies both in the United States and across the world. The main purpose of time-of-day differentials is to shift demand from peak hours to off-peak periods; however, empirical evidence suggests the degree of success is quite low. Off-peak travelers are much more price sensitive to discounts than peak travelers to surcharges. Ling (1998)

A table showing one-way fares from the current station depending on the destination and time period in Washington, D.C.

Figure 1 Fare table on a fare vending machine in Washington, DC.

further compares both pricing strategies by a few criteria including total revenue, ridership, passenger-km, and consumer surplus. Several key factors are identified that influence the choice between flat and differentiated pricing, which are the decision objective of the interested party, the initial market demand, and the demand elasticity.

Flat and differentiated pricing structures coexist in the world. For example, Washington Metropolitan Area Transit Authority (WMATA), the operator of the rail transit system in the Washington, DC area, charges a higher fare if the travel occurs in peak periods and the travel distance is larger. The fare also increases as the travel distance grows. **Fig. 1** shows a fare table from which a passenger is able to determine the fare needed to travel from the current station to a desired destination in a travel time period. By contrast, a flat fare is adopted by the New York City Subway, regardless of the travel distance or time-of-day. Different fare collection methods are used to support the flat and differentiated fares. In Washington, DC, a rail transit rider needs to tap in at the origin and tap out at the destination, while in NYC, card swiping is required only at the origin subway station.

A few theoretical studies on transit fare pricing optimization are reviewed first. Since Mohring's seminal work ([Mohring, 1972](#)) on urban bus transportation, the microeconomic modeling framework has been widely adopted and adapted to study transit pricing policies. In early studies (e.g., [Newell, 1979](#); [Wirasinghe and Ghoneim, 1981](#); [Chang & Schonfeld, 1991](#)), both the network structure and demand pattern are greatly simplified in order to solve the resulting model analytically. In such studies, fare is usually jointly optimized with other operational parameters, such as headway, bus size, route spacing, zone size, etc. When demand is assumed to be fixed, which means demand does not vary with fare or service level, usually the total cost including both the suppliers' cost and users' cost is minimized. When demand is sensitive to fare and other service parameters, the optimizing objective is to maximize the social welfare or the total profit, depending on the type of the transit operator, public, or private. Social welfare is defined as the sum of user surplus and profit. [Jara-Díaz and Gschwender \(2003\)](#) provide a review of the microeconomic models for public transit operations.

The setting of fare is also affected by the organizational structure. [Sun and Schonfeld \(2015\)](#) design a simple optimization model to show that a public operator with the objective of social welfare maximization would set fare to be equal to the marginal operating cost, which yields an operating deficit due to the fixed operating cost. The deficit is then covered by external subsidies to maintain financial feasibility. In the benchmark model, the public operator is unaware of the possibility of a negative profit and its implications. In an extended model, [Sun et al. \(2016\)](#) consider a bilevel modeling structure where the upper-level government agency provides subsidies to and imposes regulatory policies on the lower-level transit operator. Since the government agency is aware of the cost of public funds (which are mainly from tax revenues and are used to cover potential operating deficits), the passengers' surplus could be compromised to cover the fixed component of the operating cost, depending on how expensive the public funds are. The resulting fare is higher than the one adopted by a public operator, which maximizes social welfare only. [Sun et al. \(2016\)](#) also present and compare fares in other cases such as total profit maximization and break-even with 0 subsidies. [Sun and Zhang \(2018\)](#) enhance the existing literature by considering a many-to-many demand pattern (meaning transit riders travel from multiple origins to multiple destinations) and multiple user groups with different values of time and price elasticities. Through both analytical and numerical analyses, they analyze the effect of crosssubsidization: travelers who directly contribute to the capacity bottleneck are subsidized by others who do not.

In addition to theoretical analyses, there are many studies involving real-world public transit systems. [Proost and Dender \(2008\)](#) calculate the optimal transport price structure and conduct welfare analyses using data from Brussels and London. Their analyses suggest charging nearly zero transit fares in peak hours does not lead to significant welfare improvements. [Savage \(2010\)](#) conducts a time-series analysis of the Chicago Transit Authority's bus operations from 1953 to 2005 to examine the evolutions of fare and service frequency over time. One of the major findings is that more services are supplied, and higher fares are charged, than the socially optimally ones. [Farber et al. \(2014\)](#) conduct a numerical analysis to evaluate the social equity impacts of introducing distance-based fare in place of flat fare by the Utah Transit Authority. Their analyses show that low-income, senior and nonwhite individuals could benefit from the new fare structure, although the impact is not uniform geographically. As illustrated in the above studies, to determine the fare level properly, both economic, and social factors should be considered.

Public Transit Subsidization

Transit subsidies have been controversial for at least a few decades, although it is fairly common across the world to finance public transit systems in cases of operating deficits through external subsidies. In the literature, there is no consensus on the justification of transit subsidies. The so-called “Mohring effect” (Mohring, 1972) is frequently referenced as the rationale for the transit subsidy. The Mohring effect highlights the economics of scale on the user side. As more passengers use transit, additional vehicle runs are added, leading to a decreased waiting time. As more passengers might result in denser transit routes and stops, the access time may also drop. Therefore the increase in passenger demand leads to a lower travel cost for existing travelers, contrary to the usual traffic congestion effect, where additional road users decrease the overall travel speed and service quality for existing users. While transit operators provide vehicles, users also contribute to the “production” by investing their own time in travel (Savage, 2010). Because of the increasing returns to scale, the marginal cost of operating transit services is lower than the average cost and a subsidy is thus required to achieve the marginal cost pricing. Gómez-Lobo (2014) provides a synthesis of the Mohring effect.

Transit subsidies are also justified on other grounds such as positive externalities. Public transport is believed to bring a range of benefits, such as traffic congestion relief, environmental impact mitigation, and transportation emission reduction. One more rationale for transit subsidy is the second-best pricing to automobile externalities, because the use of private vehicles in congested areas and peak hours is priced below marginal cost (Elgar and Kennedy, 2005).

Despite the above-mentioned rationales, there are conflicting conclusions in both the theoretical and empirical literature regarding the necessity of transit subsidy. For further discussion on the controversy of transit subsidy see Sun et al. (2016). Even when the transit subsidy is deemed necessary, merely paying the subsidy does not guarantee that the benefits of subsidy are realized. As indicated by Else (1985), the subsidy’s effectiveness and efficiency are affected by the form of the subsidy, the operator’s objective, and its relation to the subsidizing body (e.g., government).

A few studies are then reviewed on how the subsidization scheme affects the social welfare. As a centralized optimization framework is unable to incorporate the decision interactions between multiple decision makers (subsidizer and transit operators), Sun and Schonfeld (2015) propose a bilevel optimization framework to study the effect of external subsidies and policy constraints on the transit operations. Three subsidy schemes are considered, the first two of which are based on the supply side and the third is based on the demand side. In Scheme 1, a fixed amount of subsidy is provided to the operator for each passenger trip, as a means to incentivize the operator to sustain the production level; in Scheme 2, subsidies are used only to compensate for the operating cost on the basis of passenger trips; and in Scheme 3, subsidies are provided to passengers to encourage the transit use. Three analytical models are thus formulated and solved. Such three schemes perform quite differently depending on the subsidy level and two important thresholds for distinguishing them are identified. The over-supply of services is identified under both Schemes 1 and 2, indicating inefficiencies of subsidies. Sun and Schonfeld (2015) also report that subsidization without regulation yields socially worse outcomes than the combination of subsidization and regulation. Sun et al. (2016) extend Sun and Schonfeld (2015) by analyzing the implications of the cost of public funds. They find the optimal profit is zero at optimality in their model, which means the transit operators break even after subsidies and positive profits reduce the social welfare. They also find when the cost of public funds exceeds the shadow price of the financial constraint, the subsidy is unjustified.

Next, a few empirical studies on transit subsidies are reviewed. While most other studies concluded that public transit subsidies can comprise a system’s efficiency and overall performance, despite their positive impacts on a system’s effectiveness, Karlaftis and McCarthy (1998) draw a different conclusion that there do not appear to exist a general relation between public transit operating subsidies and transit performance, based on the empirical data from 39 transit systems in Indiana, United States. In particular, the effect of transit subsidies on transit performance depends on the funding source (federal, state or local) as well as the system size (large, medium, or small). Therefore they suggest that the effect subsidies on transit performance should not be generalized. Another empirical study on fare subsidies is Parry and Small (2009), where a general framework for evaluating fare subsidies and potential pricing changes based on data from three metropolitan areas: Washington, DC, Los Angeles, and London. They find increasing subsidies beyond 50% of the operating costs can improve social welfare across modes (rail and bus), periods (peak and off-peak) and cities (all three cities mentioned above). This finding is robust to alternative assumptions about model parameters and behaviors of agencies. In short, the empirical analyses by Parry and Small (2009) demonstrate that the substantial operating subsidies for transit systems are justified based on economic efficiency. In addition, they also note that pricing automobile externalities properly could lead to significantly larger welfare improvements than transferring subsidies to public transit services. The empirical findings from Parry and Small (2009) are consistent with the findings from Nelson et al. (2007), namely subsidies to the transit systems in the Washington, DC region are well justified, because the combined benefits of rail and bus transit far exceed the transit subsidies.

It should be noted that the findings from the above reviewed empirical studies may not necessarily be generalized to other regions due to differences in regional characteristics. For instance, both Parry and Small (2009) and Nelson et al. (2007) justify the transit subsidies in Washington, DC, while Tscharaktschiew and Hirte (2012) conclude that the optimal subsidy should be small or zero in a German metropolitan area. Therefore the developed analysis frameworks should be adapted to evaluate the effectiveness and efficiency of transit subsidies based on local data.

Conclusions

Pricing and subsidization policies are central to the financial sustainability of public transit services. This article briefly discusses how public transit fare and subsidy should be optimized, covering both theoretical and empirical studies. Due to regional differences,

public transit fare and subsidy policies vary significantly. In the theoretical literature about fare optimization, a microeconomic analysis framework is usually adopted following the seminal work (Mohring, 1972). However, to facilitate the analytical solution, simplifying assumptions regarding demand pattern, price elasticity, user heterogeneity, etc. are usually made, which might not necessarily hold in the real world. In the empirical studies, in addition to various economic factors, social factors such as equity are usually incorporated in making fare policies. Transit subsidies have been controversial as conflicting conclusions usually appear in the literature, although a few rationales for subsidy have been clearly identified. There is some empirical evidence supporting the substantial transit subsidies; however, such a finding is usually difficult to generalize to other regions.

The following suggestions are made to improve the transit fare and subsidy studies:

1. Some unrealistic assumptions (for example, transit riders travel from multiple origins while to the same destination, that is, a many-to-one travel demand pattern is assumed) in theoretical studies should be relaxed for more realism.
2. Regulatory policies should be jointly considered when subsidy decisions are made, because subsidies in the absence of regulations may be counterproductive, for example, leading to wasteful overproduction.
3. Game-theoretical approaches should be adopted to fully capture the decision interactions between multiple stakeholders (regulator, subsidizer, transit operator, etc.) on the same or different levels in transit policy decision making, as the centralized decision-making process cannot fully capture the decision-making complexities.
4. Regional characteristics should be accounted for before a fare or subsidy policy is transferred across regions, as one policy that works in one region may not work in another region due to regional differences.

Definitions

Transport and urban policies have implications for multiple dimensions of social life; adequate transportation services and/or well-located housing can mean the difference between getting and keeping a job, accessing healthy food, getting to school on time, or reaching needed medical care. Decisions to build or not build specific types of transportation infrastructure in specific places can result in changes to community cohesion, exposure to air pollution, and road safety risks. The moral concern with transportation equity encompasses the multiple channels through which transport and land use policies can create conditions that allow different people to flourish, to satisfy their basic needs and lead a meaningful life.

In cities around the world, transport and mobility policies create equity issues on a daily basis. Consider the following examples:

- Bus rapid transit systems that reallocate road space from private vehicles to public transport in cities like Bogota, Dar es Salaam, and Beijing disadvantage drivers while benefiting public transit users.
- Parking and congestion pricing in London and Singapore disproportionately burden low-income drivers. But mitigating policies, like reinvesting revenue in public transit, can potentially offset any apparent disadvantage.
- An \$80-million (USD) bridge built in Sao Paulo dedicated exclusively for private motor vehicles, where public transport, cyclists, and pedestrians are prohibited exclusively benefits drivers while siphoning funds away from other modes.
- The precarious state of the pedestrian and cycling infrastructure in Nairobi, Cairo, and countless other cities across the Global South routinely creates life-threatening situations for nondrivers.
- Automobile dependency in cities like Atlanta or Houston forces low-income people and others who would prefer not to drive into automobile ownership so that they can access affordable housing as well as health and education services.
- Low-income communities and communities of color are disproportionately exposed to externalities like traffic fatalities and pollution because of their residential settlement patterns, segregation, gentrification, and displacement.

Each of these examples highlights a common aspect of transport decision making: planners and policy makers have to prioritize the allocation of scarce resources, meaning that plans and policies inevitably benefit some groups at the expense of others. Evaluating the nature and extent to which benefits and burdens differ across groups is the central core of distributive justice.

Transportation equity is a way to frame distributive justice concerns in relation to how social, economic, and government institutions shape the distribution of transportation benefits and burdens in society. It focuses on the evaluative standards used to judge the outcomes of policies and plans, asking who benefits from and is burdened by them and to what extent.

Equity as Part of a Broader Idea of Justice

Transportation equity is a crucial part of a broader concern with transport and mobility justice. Transport justice encompasses moral and political concerns related to equity, democracy, and diversity in the pursuit of more just cities and mobility systems. The concern with *equity* (distributive justice) relates to how the institutions and rules that govern society shape social and economic inequalities among its members. It focuses on the evaluative standards used to judge the outcomes of policies, asking who benefits from and is burdened by them and to what extent. Meanwhile, the concern with *democracy* relates to the fairness of the political processes related to participation in decision making. It involves the challenge of moving beyond periodic voting and overcoming technocratic top-down planning practices, and it is based on the core ideal that everyone's opinion should be equally heard in the decision-making processes that form institutions, policies, and community organizations that shape the built environment (Fainstein, 2010). Finally,

the concern with *diversity* involves the constant struggles over which rights and entitlements should be recognized and enforced. It requires the recognition of group-based differences and identities and promoting diversity in decision-making processes, acknowledging that participatory democracy is constantly marked by structural inequalities of wealth and power that marginalize certain groups and favor others in their ability to influence policy decisions (Young, 1990). Related to the concerns with democracy and diversity is the idea of the “right to the city.” This idea is undergirded by the structural uneven geographies of power and privilege in cities and the political struggles over who has the power to influence and shape urbanized space (Enright, 2019). It is broadly understood as a claim for people to reshape the processes of urbanization through collective action and self-management to complement or challenge existing government policies, or to fill a gap where there is a lack of governmental action.

Why is Transportation Equity Important?

Questions of transportation equity provide a valuable moral compass that help assess the fairness of the distribution of the benefits and burdens of transport policies (van Wee, 2011). Equity, nonetheless, is not so much about the unequal allocation of resources (transport services, investments, infrastructure) across space per se. Rather it is about how policy decisions shape societal levels of environmental externalities and what groups are more or less exposed to them, just as how they affect the lives of different groups in terms of their ability to access life-enhancing opportunities such as employment, healthcare, and education (Pereira et al., 2017).

A comprehensive understanding of transport and mobility justice requires a multidimensional effort to grasp the distributive implications of urban and transportation policies while critically examining the political processes and institutional context that determine those distributive outcomes. A research focus on transportation equity, nonetheless, is valuable in its own right. Policy choices often reflect societal biases and can widen and deepen social and spatial inequalities, and the study of social and spatial inequalities can help make visible the structural biases underlying the organization of societies and governments. Even when governments have general redistribution systems, for example through taxation policies and subsidies, implementing regressive transport policies that disproportionately benefit the well-off is not justified. Because transportation needs vary widely depending on one’s personal constraints (including mode availability, residential location, and workplace), transportation equity requires spatially targeted policies and interventions, as opposed to those that are more general and society-wide. Furthermore, public policies have a crucial role to play in social democracies through the provision of public goods and services, including public transit and large infrastructure projects. In this sense, public transport services and investments remain one of the key drivers that can shape spatial inequalities of development and opportunities in cities, making the study of the distributional effects of transport policies particularly important. Finally, even a genuinely diverse, democratic, and inclusive participatory planning process is not a sufficient condition to ensure that the outcomes of transport policies are distributed equitably. The call for transport justice goes beyond distributive concerns, and yet justice cannot be achieved without equity.

Theorizing Transportation Equity

Researchers reflecting on transportation equity are often faced with four interrelated questions about distributive justice that cannot be addressed in isolation from one another:

1. What—that is, which benefits and burdens—should be distributed?
2. On which moral principles should distributions be based?
3. What is the fairest distribution?
4. Distribution among whom?¹

Different theories of justice in the political philosophy literature (including utilitarianism, Rawls’s egalitarianism, capability approaches, and critical theories of justice) can lead to different answers to these questions. These theories are receiving increasing attention in the academic transport and mobilities literature (Davoudi and Brooks, 2014; Martens, 2016; Pereira et al., 2017). There are some general agreements in the literature about how these questions should be addressed in the context of transport policies.

Distribution of What: Benefits and Burdens

The transport literature usually focuses on four types of transport-related benefits and burdens that are related to people’s well-being: transport resources, mobility as in observed travel behavior, accessibility levels, and transport externalities (Lucas et al., 2019). Analyses of the distribution of transport resources and travel behavior can be problematic. The focus on the distribution of resources, such as car ownership or proximity to transport infrastructure, for example, can be misleading because it does not account for people’s needs and preferences, and it does not reflect people’s capability to use such resources to move in space and reach desired destinations. In turn, analyses of differences in travel behavior, such as in trip frequency or commute times, often cannot untangle how much of those inequalities emerge from individuals’ tastes and preferences (voluntary choice) or from contextual constraints outside individual control. While travel patterns are closely linked to individuals’ levels of well-being and participation in society,

¹ Questions related to the decision-making process and who has a voice in it are important but related to diversity and democracy concerns in transportation justice; they are beyond the scope of this chapter on transportation equity.

travel behavior data alone do not provide information about whether long commute times reflect constrained housing options in poor and distant locations or whether they reflect preferences for suburban living or other “expensive tastes”. Transport decisions are not always, if rarely, a matter of individual rational choice as it is often assumed in the literature.

Transportation equity studies have found more fertile ground when looking at accessibility and transport externalities. The primary benefit of transportation infrastructure and services is to improve people’s accessibility, or the ease with which they can reach key destinations including employment, healthcare, and educational opportunities. Multiple authors have argued that the concept of accessibility should be at the center of understanding transportation benefits and equity for various reasons (Martens, 2012; Pereira et al., 2017). Some minimum level of accessibility to key destinations is necessary for people to satisfy their basic needs. It also has instrumental importance to support out-of-home activity participation and the freedom of choice that allows people to develop their capabilities and flourish. Moreover, understanding the causes of disparities in access to opportunities reveals the spatial dimension in moral concerns over inequality of opportunities, which is a central theme across theories of justice but which has been largely addressed as a nonspatial problem by political philosophers and social scientists.

Accessibility is also attractive as a planning goal because it brings together transportation and land use (Manaugh et al., 2015). Because people travel to meet opportunities that are widely dispersed in space, bringing origins, and destinations closer together affects the demand for travel. These types of land use policies also support urban environments conducive to reducing automobile use and increasing walking and cycling. Such policies can also create situations where land prices and rents increase, displacing long-time residents to suburban and exurban areas. These types of secondary and tertiary effects of transportation and land use policies must be considered when attempting to meet equity goals.

One challenge with accessibility as a concept is that there is no consensus on how it should be measured (Lucas et al., 2019; Neutens et al., 2010). Most commonly in the literature accessibility is calculated by summing up the number of activities (e.g., jobs or schools) reachable from an origin location using either a defined travel time threshold (e.g., 45 min of public transit travel time) or by weighting closer opportunities more heavily. These types of measures are attractive because they can be easily calculated using readily available data. Nevertheless, a broad sense of accessibility also involves issues such as affordability, security, safety, universal design, and social practices. A more rigorous account of transportation equity should consider how accessibility levels are influenced by personal characteristics such as age, race, gender, or physical and cognitive disabilities and how such characteristics relate to local contexts of social and built environments.

Ideas about transportation system benefits have certainly shifted throughout the latter half of the 20th century in academia, but these changes are slow to diffuse to practice. The situation is most challenging in the automobile-dominated economies of the United States, Canada, Australia, and many nations in the Global South. Automobile-centric planning values travel time and specifically congestion mitigation over accessibility. The focus on reducing travel times and congestion often leads to inequitable and ineffective policies (Martens, 2016; van Wee, 2011). This is in part because the monetary valuation of travel time savings that are commonly conducted in conventional project appraisal methods (such as cost–benefit analysis) implicitly favors transport investments that primarily benefit higher-income groups. Moreover, attempts to tackle congestion and reduce travel times by adding roadway capacity ultimately leads to more congestion through a process known as “induced demand.” With reduced travel times, people make more trips or shift trips from other routes to locations that have new capacity. In the medium term, this leads to land use changes. This realization suggests that congestion is not solvable in the aggregate, but providing alternatives to driving can improve the situation for individuals. An accessibility perspective makes this clear.

Transportation equity concerns also relate to the distribution of transportation burdens, who causes those burdens and who gets exposed to them (Feitelson, 2002; Schweitzer and Valenzuela, 2004). Transportation burdens include various health-related concerns stemming from exposure to air pollution, sedentary lifestyles, and increased risk of injury and death from collisions. Most of these burdens have historically been inequitably distributed, with low-income people and people of color overrepresented in terms of their population shares of proximity to heavily trafficked roads, respiratory illnesses, and rates of injury and death. Disadvantaged populations also tend to reside in areas with lower-quality pedestrian and cycling infrastructure and where traffic conditions are more dangerous, subjecting them to increased risk of death or severe injury when collisions occur. On the other hand, studies have shown that high-income populations are disproportionately responsible for flights and private vehicle use, which are responsible for overwhelming shares of transport pollution (Mattioli, 2016). Efforts to mitigate these disparities have been uneven. In Global North countries, air quality has been steadily improving over time even as levels of driving continue to increase. In the Global South, on the other hand, rising automobility, the use of older vehicles for longer periods of time, and unfavorable geography, have all contributed to dramatically worse air quality in places like Beijing, New Delhi, and Santiago.

Efforts to mitigate these health concerns can sometimes have unintended consequences. For example, a popular approach to increasing traffic safety includes adopting “Vision Zero” policies that have as their goal reducing or eliminating traffic deaths. A popular method for achieving Vision Zero in cities around the world involves increasing police presence in locations where traffic incidents are concentrated. But these also tend to be locations disproportionately populated by disadvantaged populations. Cyclists in particular are vulnerable when police presence increases because they are often violating laws (either knowingly or unknowingly) as a matter of necessity or because of financial constraints. Riding on the sidewalk to avoid heavily-trafficked streets is one example. Riding without lights or a helmet is another. While lights are often required while riding at night, they are somewhat costly to maintain because they require batteries and are easy targets for theft. These minor legal violations give police an opportunity to stop, question, and potentially search cyclists. Depending on demographics, the presence of a cycling culture, and infrastructure, the types of people bicycling will differ substantially. Attitudes toward cycling will also tend to differ. In many locations in the United States,

for example, cycling is a deeply marginalized choice and this is reflected in the demographics of those who choose to ride. Increased policing and enforcement can produce a very dangerous situation for these cyclists.

Guiding Moral Principles

Regardless of the specific benefits and burdens that are considered as part of an inquiry into transportation equity, applying different moral principles will result in different understandings about how such benefits and burdens should be distributed. Two broad types of moral concerns that are commonly applied in the transportation equity literature but rarely explicitly articulated come from sufficientarian and egalitarian perspectives.

A sufficientarian approach to justice considers whether the distribution of goods and bads in society allow everyone to meet a generally acceptable standard of living. Stated differently, absolute levels matter more than relative inequalities for sufficientarianism. Adherents would not be concerned with differences across groups, as long as all achieve above a certain threshold of, say, transport accessibility or air quality (Martens, 2016).

Sufficientarian concerns are reflected in various ideas that permeate the transportation literature and practice. Much attention has been given to issues related to environmental justice and public health, looking for example at whether certain ethnic minority neighborhoods and other vulnerable groups are exposed to exceedingly high levels of transport air pollution. A growing body of research also focuses on the ideas of “needs gaps” and “transit deserts.” These studies seek to quantify a “gap” between the level of public transport service (supply) and the needs of a particular population (demand), and identify as “deserts” those locations where demand outpaces supply levels. Most of these researches are not explicitly grounded in theoretical frameworks on justice or basic needs, even though they take an implicitly sufficientarian perspective without naming it as such. These studies depart from the idea that there exists a minimum level of transport resources, services, safety, or accessibility that is necessary for people to fulfill basic needs and lead a meaningful life, or conversely that there is a maximum amount of transport externalities such as air pollution that is deemed acceptable. A corollary to this idea of a minimum standard is that public action is necessary to guarantee the needs of people who fall below that threshold.

In contrast to sufficientarians, egalitarians are fundamentally concerned with the relative distribution of goods and bads among members of society. From an egalitarian perspective, for example, even if all individuals in a city had above acceptable levels of access to job opportunities by public transport, for example, this situation would still be deemed unfair if a population group had relatively lower access as a result from a discriminatory policy against them. This is a strong reason why transport justice problems cannot be defined solely based on sufficientarian concerns. Egalitarianism encompasses the idea that all individuals have equal moral worth and should be treated as equals in some respect, even though different theories of justice might disagree about what kinds of equality (resources, life outcomes, well-being, opportunities, etc.) are more morally relevant.

Transport inequalities are a common egalitarian concern found across the transport equity literature, even though the majority of this research is not explicitly grounded on any theory of justice. Typically, studies in this tradition investigate, for example, the extent to which certain groups or neighborhoods are disproportionately more exposed to transport externalities or why certain groups are better served by public transport and have higher transport accessibility levels than others (e.g., Bullard and Johnson, 1997). The implication is that these inequalities could reflect deeper structural factors such as historic discriminatory policies and other disadvantages that undermine the transport experience of certain groups and further exacerbate injustices.

A fair transport policy is guided by both sufficientarian and egalitarian concerns. It aims to improve, for example, overall levels of transport safety or accessibility and reduce transport externalities so that everyone is above acceptable thresholds, while at the same time prioritize improving the conditions of disadvantaged groups and reduce inequalities. However, promoting minimum levels of transport goods/bads and reducing inequalities, is not sufficient to guarantee a just urban and transport policy. A necessary condition for a policy to be considered fair, is that it cannot not override the basic rights and liberties of individuals and minority groups even if it promotes a greater good to a greater number of people (Pereira et al., 2017). Particularly in Global South, it is still more often the norm than the exception that governmental officials use this type of utilitarian discourse to justify the eviction of poor communities in order to expand road and transport infrastructure.

In summary, a fundamental characteristic of an equitable transport policy or project is that its implementation respects people’s basic rights and liberties, such as the physical and psychological liberty and integrity of the person. Furthermore, it should both prioritize improving the conditions of disadvantaged groups and reduce transport-related inequalities, and at the same time account for people’s basic needs ensuring that all individuals achieve above a certain threshold of essential transport goods/bads, whatever those thresholds may be given a set of environmental constraints. On the whole, this sets a theoretical framework that is flexible enough to accommodate universalist concerns about the protection of basic rights, the satisfaction of basic needs, and promotion of equality of opportunities without losing sight of context-specific issues regarding the particularities of each urban context and that the notions of basic needs and minimum thresholds are historically and culturally dependent.

What is a Fair Distribution?

These moral concerns of egalitarianism and sufficientarianism suggest whether relative or absolute levels of goods and bads should be considered, but these principles alone do not determine whether a specific distributional outcome is judged to be equitable. Studies that follow a sufficientarian perspective often adopt a technocratic approach and assume implicitly the minimum levels that require policy intervention can be defined through a “technical” decision based on empirical data analyses alone, without any moral

or political judgment. Nonetheless, the definition of what an “adequate” level of transport accessibility or externality means is ultimately a political decision that deeply reflects the vision of a just city and mobility system each society aspires to build and which is highly dependent on local and historical context. For policy purposes, setting those thresholds ultimately requires a legitimate political and democratic process.

Studies that take an egalitarian stand, on the other hand, generally do not specify why the transport inequalities they analyze should be deemed unfair and implicitly assume the mere existence of any inequality is put forth as evidence of unfairness. One standard that could be used when defining whether a given transport inequality should be deemed inequitable is whether an observed disparity results from the unfair treatment of disadvantaged groups and whether such inequality could undermine/compromise their life chances. It is not the level of inequality per se that determines whether a given distribution is inequitable, although oftentimes this magnitude can be very telling of deeper injustices.

Moreover, studies that focus on transport inequalities, as a rule, do not clearly state how far policies should go to mitigate them. At the outset, it is important to note that a situation of perfect equality (whether of transport resources, services, accessibility, etc.) is not possible because of how societies are (spatially) organized, even if some might consider full equality to be desirable. Nonetheless, there is a growing consensus in both transport planning practice and in the academic literature that a fair transportation policy should prioritize improving the conditions of people in the worst-off positions, helping to pull them above acceptable minimum thresholds and reducing inequalities (Pereira et al., 2017). Despite various differences of ideas between and within egalitarian and sufficientarian views of justice, it is commonly accepted that equality does not necessarily equate with equity and that in some cases the pursuit of justice requires that individuals or groups be treated differently to compensate for unfair conditions and inequalities. This is one of the reasons why it becomes increasingly important to move beyond cross-sectional descriptive analysis of transport poverty and transport inequalities, and look more closely at how and to what extent the implementation of various policy interventions can contribute to promote fairer and more inclusive cities and mobility systems.

For Whom?

Each of the prior considerations can be set without consideration of specific population groups for whom outcomes should be assessed and compared. The literature and practice have very clearly focused on population groups known to be disadvantaged because of low income, ability, and historical discrimination (Lucas, 2019). For example, relevant groups include youth, older adults, women, low-income people, zero-vehicle households, people with disabilities, single-parent households, refugees, and racial/ethnic minorities. There is a common understanding that these are morally arbitrary characteristics, beyond individuals’ control, but which often undermine people’s transport experience because of historic discriminatory policies and other disadvantages. This emphasis in the literature also arises in part from the sense that these groups have been historically excluded from the transportation planning process as well as legal frameworks that require transportation planners to explicitly consider their needs (Grengs, 2002; Karner and Niemeier, 2013).

Transportation disadvantages can manifest in various ways (Lucas and Jones, 2012; Mullen et al., 2014). They occur when there are not enough transport resources/services available to an individual or household for them to participate in desired activities. They can also occur when there are enough resources/services but these are inadequate for people with disabilities. Transport disadvantages can also occur when vulnerable groups are disproportionately exposed to environmental externalities, or when the transport experience, physical and mental health of a person or group are undermined, limited or put at risk because they are from an ethnic minority or gender in a given social and built environment. While a few studies use the term “modal equity” to refer to inequalities between transport modes, equity is about people. Disparities between transport modes (say of road space, or accessibility, etc.) only become equity issues because of the systematic differences in the socio-demographic characteristics of those who predominantly reap the benefits and bear the externalities of different modes.

Although there is no absolute standard for when a particular situation rises to the level of disadvantage, researchers have identified that *social exclusion* can result if transportation needs are not met. This situation can result in trips being foregone with attendant poor outcomes including difficulty finding and keeping a job, inability to reach medical care, difficulty accessing educational opportunities, and limited social connections. Historically disadvantaged groups in a transportation equity context are disadvantaged because of their risk of social exclusion (Lucas, 2019).

A transportation equity perspective that focuses attention on the needs of these groups is important because transportation planning has historically responded to the needs of the most mobile and has sought to further improve their mobility. This emphasis is most clear in the automobile-oriented transportation planning that has commonly occurred in Canada, Australia, and the United States and across countries in the Global South.

Legal frameworks in the United States that respond to that country’s unique and problematic history of racism, unequal treatment, and discrimination against people of color require public agencies to ensure that their policies and practices are not discriminatory (Bullard et al., 2004), although the methods agencies use to demonstrate nondiscrimination can often be inconsistent with best practices developed in the academic literature (Karner and Niemeier, 2013). The Americans with Disabilities Act (ADA) also requires agencies to provide equal accommodations for people with disabilities, but this often manifests in paratransit services that are viewed as a lower tier than fixed-route options. In the early 1990s, the United Kingdom made strides in efforts to combat social exclusion, forming an official government arm to implement policy across a number of issue domains, including transport. Difficulties with developing appropriate transport-specific metrics and tying them to real-world planning efforts meant that that effort did not result in material gains on social exclusion.

The Future of Transportation Equity

The pace of technological change in transportation is creating profound disruption and dislocation across the industry that challenges existing frameworks related to transportation equity. Questions regarding the appropriate role for private organizations in providing mobility, the effects of connected and automated vehicles on public transit provision, the desirability of “micro” transit and on-demand transit services, and the role of bike share and other “micromobility” solutions on travel outcomes all warrant increasing attention.

In the coming decades, the transport industry will increasingly rely on algorithms to support the planning, management and allocation of automated vehicles, and mobility services, for example with the use of artificial intelligence and big data predictive modeling to develop flexible routing and scheduling of services. There is a growing awareness of the ways in which big data and algorithms often reflect the biases underlying broader social and political processes. The lack of critical reflection and algorithmic transparency raises the risk of decision-making processes that inadvertently reflect those biases and end up reinforcing injustices. While much of the current research on automated vehicles and shared mobility systems focuses on how to make them commercially viable, more research is needed to understand how these changes in technology and governance will reshape who gets access, when, and how, and what implications they might have for questions of equity, public health, and environmental justice.

In the meantime, the rise of transportation network companies (TNCs)² is already leading directly to declines in public transit ridership in cities around the world. TNCs operate best when there is a high density of origins, destinations, and potential riders, so that wait times are minimized. Locations where these conditions prevail are also those where public transit is most likely to succeed. The practical result has been diminishing public transit ridership and increasing congestion in cities where TNCs have been active the longest. Some observers have hailed this development as another example of successful “disruption” of an outdated public transit business model. What these observers fail to realize is that public transit provides essential lifeline mobility to those who need it most in locations that would otherwise be unprofitable to serve. Private mobility providers simply cannot be relied upon to serve the diversity of markets that public transit serves. Indeed, public transit operators intentionally provide service in locations that they know will not generate a profit so that residents have some access to transportation services. They also operate large vehicles to accommodate peak travel demand, minimize maintenance challenges, and streamline driver licensing and certification.

The influx of private mobility providers into markets previously served by public transit has led to a push for increasing “microtransit” or on-demand service. The problem with these calls is that microtransit does not scale well. Where public transit is most effective, operators save time by not deviating from a fixed route to reach every user at their origin and destination. Instead, they collect riders at common origins and destinations, with riders required to complete the first and last mile. A microtransit system that provides every customer with door-to-door service would create substantial unreliability and unpredictability at relatively modest levels of demand. It may provide a viable option in certain types of first/last-mile situations and in areas where public transit demand is relatively low.

A perennial issue with TNCs as a transportation equity measure involves the problem of un/underbanked populations and smartphone access. Access to credit is often a prerequisite for using the smartphone apps that enable TNC access and many lower income people simply do not have access. While smartphone penetration rates continue to increase across all population groups, limitations on data plans are more likely to affect low-income people and thus their ability to access private mobility providers. Spatial discrimination also continues to be a problem, with evidence of TNC drivers avoiding certain neighborhoods out of real or perceived fear.

One response to the challenges of public transit in general is to provide automobiles to those experiencing transportation disadvantages in an effort to mitigate their social exclusion by encouraging automobility. Multiple researchers have examined the effect of such a policy on outcomes and the results are promising. Providing low-income people with cars increases the likelihood of finding and keeping a job and can lead to long-term increases in earnings. The problem, unfortunately, is that this solution also does not scale and come at an environmental cost (Mattioli, 2016). Giving all low-income people cars will saddle already vulnerable households with additional debt and monthly costs that may or may not be offset by increased revenue, increase risks of injury and death, and accelerate the climate crisis. Additionally, the cities that have grown up around automobility run contrary to the basic principles of city building that have accumulated over decades, increasing car dependency and thus limiting mobility and accessibility choices for nondrivers.

Indeed, urban planners are concerned with understanding the types of places people want and how to create them. Encouraging more driving cannot be the solution to transportation equity issues (Mattioli, 2016). More promising alternatives that address equity without exacerbating the climate crisis and leading to unintended health consequences are possible but they involve looking beyond transport to consider land use, housing, and institutional barriers in an integrated manner. Despite the knowledge that travel demand is intimately related to land use, transport practitioners still rarely consider housing and land use solutions to transport problems. Creating places where people do not have to use the car to access and hold a job, where they can make healthy transport decisions, and where their share of household income allocated to transport and housing is held to a reasonable level is a more promising—and proven—strategy for achieving transportation equity that does not rely on the benevolence of private entities nor does it require us to rely on the game-changing promise of new technology. To achieve transportation equity, we need to ensure that all residents of our cities and regions can safely reach the opportunities that they need to thrive.

² Various referred to as ridehailing, ridesourcing, and (incorrectly) ridesharing organizations, these are companies that provide users with the ability to summon a vehicle to serve a trip on demand.

Cost-Benefit Analysis

Cost-Benefit Analysis (CBA) is a widely used economic appraisal method, which aims to support policy makers in making decisions about projects and policies (Boardman et al., 2013). In virtually all western countries CBA is mandatory when national funding is asked for large transport projects (Mackie et al., 2014). The theoretical foundations for CBA are provided by welfare economics, which is a branch of economics that investigates the social desirability of alternative economic situations (Boadway, 2006). The CBA is built on the Kaldor-Hicks efficiency criterion, which recommends projects where the sum of monetary gains outweigh the sum of monetary losses and winners can potentially compensate the losers (The Pareto and Kaldor-Hicks criteria; Minken).

In a CBA, positive and negative impacts of government projects are valued by estimating private willingness to pay (WTP). Transport projects are typically intertemporal in nature, so the benefits and costs occur over a number of periods. Because people tend to prefer a present dollar over a future dollar—even after a correction for inflation—future impacts of the project are discounted and presented as so-called (net) present values (Mouter, 2018) (The social discount factor; Hultkrantz). Although the core principles of CBA are universal across countries research shows that there is a considerable spread in the price tags in the appraisal guidelines of OECD countries (e.g., the value of time (VOT), the value of a statistical life (VSL), and the valuation of CO₂) (Mackie et al., 2014).

Formal Role of CBA

The formal role of CBA differs between countries. In practices, such as Chile, the United Kingdom, and the Netherlands, CBA provides information for decision-making about the extent to which funding is approved for a specific transport project (Gomez-Lobo, 2012; Mouter et al., 2013). On the other hand, in practices, such as Sweden and Norway CBA is formally used to rank large numbers of transport investments against each other (Eliasson et al., 2015). In these countries, CBA is primarily used for choosing investments from a shortlist of suggested investments given a total available budget. Hence, it is the relative ranking of investments that is of importance, rather than the absolute level of the net benefits.

The demand forecasts, cost estimates, benefit valuations, and effect assessments that are conducted as part of CBAs are all subject to various degrees of uncertainty. Hence, the question is, given such uncertainties, how robust the policy conclusions of CBA are. Using simulations based on real data on national infrastructure plans in Sweden and Norway, scholars studied how investment selection and total realized benefits change when decisions are based on CBA assessments subject to several different types of uncertainty (Asplund and Eliasson, 2016; Börjesson et al., 2014) (Robustness of CBA; Welde and Odeck). Their results indicate that realized benefits and investment selection are surprisingly insensitive to all studied types of uncertainty, even for high levels of uncertainty.

Impact of Transport Cost-Benefit Analysis on Public Decision Making

Several researchers tried to uncover the extent to which CBA actually impacts decision-making by investigating the statistical relation between the results of CBA studies and political decisions on investments in transport infrastructure using quantitative analyses (Annema et al., 2017; Eliasson et al., 2015; Fridstrøm and Elvik, 1997; Odeck, 2010). The broad picture is that these studies show that there is no significant statistical relation between the monetized effect estimations in CBA studies and political decisions. The exception is the Swedish Transport Administration's selection in the construction of the Investment Plan 2010–21, which seems to be strongly affected by CBA results (Eliasson et al., 2015). However, although decisions of Swedish civil servants were strongly affected by the CBA outcome of transport projects, politicians' decisions were only weakly affected, and only for small projects.

Furthermore, several studies have analyzed how politicians use CBA in the context of transport investment decisions by interviewing politicians (Mouter, 2017a,b; Nyborg, 1998; Sager and Ravlum, 2005; Sager and Sørensen, 2011). These qualitative studies conclude that CBA is at best one of the factors that influences politicians' judgments. None of the politicians interviewed in these studies stated that they solely base their judgment on the results of CBA studies. When politicians use CBA in forming their standpoint, it is most likely that the results affect their viewpoint about the desirability of different alternatives of a specific transport project (Mouter 2017a). Especially when a politician supports a project, but does not have a strong preference for one of the alternatives, there is a chance that the CBA affects the desirability judgment of the politician regarding this particular decision. In countries in which CBA is formally institutionalized as a ranking tool, politicians use CBA as a screening device to pick projects requiring closer political attention, but few seemed to actually use it to rank projects (Nyborg, 1998).

Various studies investigate the role that the CBA has played in decision-makers' choices between light rapid transit (LRT) and bus rapid transit (BRT) (Nicolaisen et al., 2017). These studies establish that both in Denmark, France, and the United Kingdom decision makers choose for LRT systems instead of BRT systems even though LRT systems score relatively poorly in CBA studies. Decision makers justify their choice for LRT systems in terms of the branding value, positive image for public transportation and the perceived provision of viable, affordable and attractive alternatives to the automobile, while contributing to more liveable and sustainable cities.

Opportunistic and Symbolic Use

It is more likely that politicians use a CBA as ammunition in discussions with other politicians than as an input for their desirability judgment of transport projects (Mouter, 2017a; Nyborg, 1998). When the CBA does not support a politician's opinion she will criticize the study and she will emphasize the importance of CBA when the results support her opinion, even when she did not use CBA in forming her opinion at all. The literature also identifies that politicians use CBA to make themselves and their decisions look more rational which is also called: "symbolic use" (Sager and Ravlum, 2005; Mouter, 2017a). The institutionalization of CBA has symbolic value for politicians, as the search for and processing of information may itself send out signals that will enhance the status of the political body. In Norway, for instance, researchers observed that the main function of CBA—and analytic planning input in general—was to legitimize the Norwegian Transport Plan and the political process related to it (Sager and Sørensen, 2011). Politicians must be able to show the public that the output of expert analysis was available to them when they made their decisions, so it can be credibly stated—should the need arise—that expert advice was considered as part of the policy-making.

Particularly executives (e.g., ministers) use CBA as a means for depoliticizing the political debate. In this case, CBA is used as a "rational argument" to support the wishes of the executive. In the Netherlands, it was found that top-level civil servants pursued to produce a set of rational arguments, which supported all of the executive's preferred decisions in a consistent way, which makes it difficult for the political opposition to challenge the consistency of the executive's decisions during a debate (Mouter, 2017a). These civil servants aimed to avoid any inconsistencies in argumentation as this can force an executive into revealing her real (irrational) argument for (not) supporting a project, which is an unwelcome situation, as in general, rational arguments are more convincing than emotional arguments.

Barriers Hampering Politicians' Use of CBA When Forming Their Judgments

The scientific studies in which politicians were interviewed about their use of CBA identified several barriers, which need to be rectified to increase politicians' use of CBA when forming their judgments. A first important barrier, which limits the use of CBA by politicians, is that they don't have enough trust in CBA's impartiality (Mouter, 2017a). Politicians do not seem to think that results of CBAs are deliberately manipulated, but they have the idea that CBA analysts implicitly and even unconsciously make political choices while carrying out a CBA which influences (the communication of) the results (Mouter, 2017a; Nicolaisen, 2012). For instance, politicians believe that in cases in which analysts can make a choice between multiple assumptions which all are defensible, they can be tempted to choose the assumption that best fits the interests of the institution who orders the CBA (Mouter, 2017a). Moreover, politicians believe that analysts also have their hobby horses (e.g., positive about public transport), which can unconsciously bias the assumptions they make when conducting a CBA. Note that politicians who genuinely trust CBA's impartiality may criticize the method on this ground when the CBA does not support their pet project (see Section, Opportunistic Use) and vice versa it is possible that politicians who genuinely distrust may use the results of a CBA in a public debate when the study supports a project they want to push through the system.

A second important barrier is that politicians often receive the CBA too late in the process to (substantially) influence their viewpoint (Mouter, 2017a). Generally, key decisions regarding transport projects—and sometimes also political promises—are made in the early stage of the policy cycle. In this phase, it is highly likely that decision makers merely receive information about the transport project and the problem it needs to resolve from lobbyists or from a first-hand look during a site visit. Decision makers are presented with CBA results at the end stage of the policy cycle. In the Netherlands, it sometimes even happens that Members of Parliament receive a CBA study a few days before the decisive parliamentary debate regarding the transport project (Mouter, 2017a). In those cases it is highly unlikely that a CBA would have any impact on political decisions. Among Dutch politicians, there is a consensus that a CBA should be published 2 months before a debate to have any impact on the decisions being made during the

debate. This will give politicians enough time to discuss with their colleagues whether the results of a CBA should lead to a reconsideration of a viewpoint. Moreover, the publication of a CBA long enough before a political debate enables politicians to ask a confidante to verify the study, which increases their trust in the results.

A third barrier is that politicians assign a relatively low weight to the results of a CBA in their judgments because they contest CBA's normative premises (Mouter, 2017a; Nyborg, 1998). Politicians are of the view that as a result of the discrepancy between the premises of CBA and their belief system, projects which coincide with their own belief system score relatively poorly in CBAs.

The first normative decision analysts need to make when conducting a CBA concerns the individuals that are (not) included in the analysis, which is also known as the question of "standing." CBA generally adopts a welfarist approach to social evaluation, which means that the preferences of individual citizens form the basis of a CBA (Sen, 1979). This implies that costs and benefits for animals, and nature in general, only count when humans value them (Baum, 2009). This normative choice might not be in line with the belief system of politicians from Green Parties.

A second normative decision concerns the weighting of the preferences of different individuals when establishing the social welfare effect of the project. Economists use a social welfare function, as a formal representation of the value judgments regarding the emphasis society should place on the interests of different citizens. In essence, the question is whether the social welfare function is utilitarian (an equally large weight is attached to everybody's utility changes regardless of their current situation) or non-utilitarian (utility changes of citizens receive a different weight when determining the social welfare effect of a government project). The common approach in practice is to postulate a utilitarian social welfare function. The fact that CBA generally postulates a utilitarian social welfare function is often criticized in the academic literature for ignoring distributive justice considerations that are important for political decision-making (Nyborg, 2014).

Studies investigating political decision-making regarding transport projects established that politicians particularly regard "spatial equality" of transport investments as a key consideration in their decisions involving the allocation of investments in a national transport program for infrastructure investments (Mouter et al., 2017). For instance, politicians perceive that transport projects in densely populated areas perform better in CBAs than projects in sparsely populated areas as a result of the normative assumption in conventional CBAs that equal weight should be assigned to the utility effects of every individual in a society. These politicians, however, argue that it is fair to balance transport investments across the country to some extent, because all over the country citizens pay taxes, which makes it justifiable to improve citizens' mobility all over the country. More formally, politicians assign a higher (lower) weight to benefits of transport investments in regions, which receive relatively less (much) benefits from the national transport investment program in their social welfare function.

Analysts could deal with the inevitable value judgments implicit in CBA by communicating these judgments in a transparent way. Interestingly, politicians seem to prefer, on the one hand, that all calculations in the CBA are done in an impartial way and, on the other hand, they want the inherent partiality of the method to be recognized by making it explicitly clear which value judgments are made (Mouter, 2017b). Hence, the ideal situation seems to be that politicians can trust that analysts executed the calculations in an impartial way, while being aware of the value judgments implicit in the CBA. Apart from improving transparency regarding normative assumptions in CBA, scholars argue that a CBA report can serve politicians who disagree with the value judgments through providing supplementary information. For instance, politicians can be provided with information regarding the spatial distribution of transport benefits accruing from an investment program to better enable them to consider both the aggregate benefits of the investment program and the distribution of benefits across regions in their decisions.

What Explains the Positive Attitude of Politicians Toward CBA?

Although the results of a CBA do not seem to substantially impact decision-making in a political environment, academic studies universally find that politicians and civil servants have a positive attitude toward the institutionalization of the method (Nyborg, 1998; Mouter, 2017b). Studies which analyzed politicians' and policy makers' attitudes toward CBA in the domains of flood protection and environmental regulation find the same results (Dehnhardt, 2013; Hahn and Tetlock, 2008). The institutionalization of CBA can bring several benefits to decision-making on transport projects. The literature distinguishes at least eight categories of positive features of CBA.

First, CBA is based on a rigorous theoretical framework being welfare economics that allows for the trade-off between money and social impacts. The principles of welfare economics provide CBA researchers and users with a very clear frame of reference when reflecting on the impacts of policy measures that should (not) be included in a CBA, and how these impacts could be measured and monetized. This is a clear advantage compared to methods such as multi-criteria analysis, which are not build on such a rigorous theoretical framework (CBA versus multicriteria analysis; Beria).

Second, CBA enhances the attention given to citizens' interests in the political process. Two important value judgments underlying welfare economics and CBA are "individualism" and "non-paternalism." In combination, these postulates assert that the welfare impacts of individual members of society resulting from the project form the basis for establishing the societal welfare effect (individualism) and individuals are conceived to be the best judge of their own welfare (non-paternalism). Because impacts for citizens and firms, and not the interests of stakeholders, academics or policy makers, are the focal point of a CBA analysis, the instrument is also known as the "tax payers only model of representation at the political negotiation table."

Third, CBA can be an antidote to overcome cognitive limitations and biases from causing policy-makers to neglect vital aspects of proposed policies. This is also known as "the cognitive argument for CBA." (Sunstein, 2000) Politicians may face hundreds of

projects, and it is simply not possible to completely process all these options. In such situations, humans are bound to use simple heuristics and appraisal tools such as CBA make it easier for politicians to structure information and remember and consider all or most aspects of a suggested project. Politicians think that this is advantageous because it can prevent them from forgetting to consider important consequences for citizens and firms in the decision-making process.

Fourth, CBA is considered to be a useful building block for forming an opinion regarding public projects because the method provides insights into the order of magnitude of positive and negative impacts of a project by translating these effects into money. This provides guidance when making decisions. When the societal costs of a project are (substantially) higher than the benefits this can alarm politicians to not support a project. Fifth, due to standardization and the fact that the final indicators of a CBA (e.g. the benefit-cost ratio) communicate very clearly, CBA makes projects comparable. Sixth, CBA can enhance the sharpness of political debates and the underpinning of political decisions. That is, politicians have found a need to argue in a more precise way about why they want a project despite a negative CBA, or why they don't want a project despite a positive CBA. Dutch politicians argue that without a CBA, quite frequently, the necessity of a government project is underpinned in a very general way. The result of a very negative CBA is that these general arguments will be contested in political debates by politicians opposing the project. For instance, with regard to the negative CBA results of light rapid transit (LRT) it was found that decision makers made great efforts to emphasize and inscribe the strategic values of the projects, not included in the CBAs, into diagrams, reports, maps, etc., in order to visualize and make these values "real" for decision makers (Nicolaisen et al., 2017).

Seventh, civil servants use CBAs to optimize infrastructure projects in the early phases of their planning process. Finally, CBA can act as a filter (gatekeeper) to prevent weak projects proceeding very far through the planning process. For instance, civil servants from higher tier governments use a negative CBA as an argument in discussions with civil servants from lower tier governments to clarify that it would be better not to have any high expectations about receiving a national contribution for the project because of the poor CBA score (Mouter, 2017b). Hence, in this process, many projects are terminated before they even reach national executives.

Biography

Niek Mouter is an assistant professor in Infrastructure Project Appraisal at Delft University of Technology, the Netherlands, faculty Technology, Policy, and Management. His research primarily revolves around two research lines: (1) The inclusion of equity and other ethically important considerations in the appraisal of infrastructure projects in general and Cost-Benefit Analysis in particular; (2) Improving the usability of Cost-Benefit Analysis for policy makers. He (co)developed a novel assessment approach called "Participatory Value Evaluation."

Introduction

The objective of ex post evaluation is to quantify retrospectively the impacts that interventions have had on defined outcomes of interest. In the transport domain, such evaluations can be made in relation to almost any type of “intervention,” including physical projects, regulations, price changes, or other policy initiatives.

Our presupposition is that evidence from ex post evaluation is useful only when it points to a *causal*, rather than merely associational, relationship between intervention and outcome. Ultimately, we want to be able to identify effects that arose due to a course of action taken, relative to some other course of action that was not pursued (often no intervention). For transport evaluation, data are observed rather than generated experimentally and this limits our ability to compare outcomes under different treatment regimes. Furthermore, transport interventions are typically nonrandomly assigned and this obscures causality further. To infer cause-effect relationships in these settings, we require an appropriate causal inferential framework for identification and statistical modeling methods appropriate to the data in hand.

In this chapter we review statistical approaches for ex post evaluation of transport interventions that can be used to infer cause-effect relationships from observational data. The aim of these *causal inference* techniques is to quantify impacts that have explicitly occurred due to intervention (or “treatment”). Comprehensive reviews of the statistical principles and methods underpinning causal inference are provided by van der Laan and Robins (2003), Imbens and Wooldrige (2009), Imbens and Rubin (2015), Pearl et al. (2016), and Abadie and Cattaneo (2018). Through ex post evaluation we can assess how well resources have been allocated in the past according to some defined metrics of interest, and crucially we can also construct informed forecasts of the impacts that transport interventions may have in the future.

The chapter is structured as follows. Transports interventions and outcomes defines key concepts in causal inference. Ex post evaluation and the potential outcome framework for causal inference introduces the potential outcome framework for causal inference as a working model within which to conceptualize ex post evaluation. Ex post evaluation via model-based adjustment for confounding and Ex post evaluation under a nonignorable treatment assignment review techniques for treatment effect estimation under ignorable and nonignorable treatment assignment conditions respectively. Summary summarizes and concludes.

Transports Interventions and Outcomes

Ex post evaluation aims to quantify the causal effect of a transport intervention, or set of interventions, on an outcome of interest. Typically, we seek to compare the intervention outcome to other “counterfactual” scenarios, perhaps involving no intervention or some alternative intervention. It is important at the outset to define these two key concepts of *intervention* and *outcome*.

Interventions, termed “treatments” in the literature, are defined in the broadest sense to encompass any conceivable manipulation of the transport system. For instance, a treatment could involve the construction of a new link, an expansion in transport capacity, the imposition of a new regulation, a change in transport prices, a change in the frequency or quality of service, and so on. Treatment variables can thus be binary, multivalued, or continuous. Table 1 gives examples of transport interventions classified as treatment variables.

Table 1 Transport interventions classified as treatment variables

<i>Binary treatment</i>	<i>Multivalued treatment</i>	<i>Continuous treatment</i>
+ Δ capacity/no Δ capacity	Number + Δ capacity routes	Length of + Δ capacity
New network link	Number of new links	Distance to new link
New station	Number of new stations	Station accessibility metric
Tolled/untolled route	Number of tolled routes	+ Δ % price on tolled routes
Introduction of speed camera	Number of speed cameras	Speed cameras per km ²
Train service/no train service	Train service headway	Train pax. capacity
Peak service/off-peak service	Number of peak services	% of service in peak

Outcomes represent phenomena that we believe a-priori will respond to manipulation of the transport system. Outcomes of interest could measure traffic conditions (e.g., speeds, flow, safety, congestion), economic characteristics (e.g., output, productivity, growth), mode shares, environmental consequences, social concerns, and so on.

The relationship between outcomes and interventions are analyzed for *units* of study, normally defined by the data available for analysis. Units could be geographical zones, network links, people, households, firms, or cities.

In addition to outcomes and interventions, for ex post evaluation we often make use of a third source of data on measured characteristics of units. While our fundamental concern is on the effect of the treatment on the outcome, we also recognize that the units under study are heterogeneous and that this could be relevant in making comparisons. So, we use data on unit characteristics to measure and adjust for relevant differences between units.

Ex Post Evaluation and the Potential Outcome Framework for Causal Inference

Using the definitions just provided, we can represent the typical set up for ex post analyses as one in which the data available for evaluation are realizations of a random vector, $Z_i = (Y_i, D_i, X_i)$, where for our n units of observation, $i = (1, \dots, n)$, Y_i denotes a response (or outcome) of interest, D_i is the treatment (or exposure) received (i.e., a transport intervention), and X_i is a vector of pretreatment covariates describing characteristics of the units under study. As mentioned previously, treatment variables can be binary, (i.e., $D \in \{0, 1\}$); multivalued, in which dose d can take values in m categories $D \equiv (d_0, d_1, \dots, d_m)$; or continuous with dose d taking values in $D \subseteq \mathbb{R}$.

The objective of ex post evaluation is to quantify the effect of treatment on outcome. A useful working model for this type of inferential problem is offered by the *potential outcomes* framework for causal inference. Under this approach, we define our target of inference not simply in relation to the outcomes that we actually observe, but also in relation to those that could potentially have been observed under different courses of action (counterfactuals). Specifically, we define the Average Treatment Effect (ATE) as the estimand of interest, which in the case of binary treatments, is the difference in average outcomes under intervention and nonintervention, $\tau(1) = E[Y_i(1)] - E[Y_i(0)]$, where, $Y_i(1)$ and $Y_i(0)$ are the *potential outcomes* for unit i under treated and control status, respectively. In the case of continuous and multivalued treatments the ATE takes the form $\tau(d) = E[Y_i(d)] - E[Y_i(0)]$, for any dose of interest d .

The observed data reveal only actual, not potential, outcomes. Thus, in the case of binary treatments we observe the random variable $Y_i = Y_i(1)I_1(D_i) + Y_i(0)(1 - I_1(D_i))$, where, $I_1(D_i)$ is the indicator function for receiving the treatment, but we do not observe the joint density, $f(Y_i(1), Y_i(0))$, since the two outcomes never occur together. Similarly, for a continuous or multivalued treatment we observe only $Y_i(D_i)$, and outcome at all other levels, $d \neq D_i$, are unobserved or *counterfactual outcomes*.

The fact that we cannot observe all potential outcomes means that *individual causal effects*, for example, $Y_i(1) - Y_i(0)$ or $Y_i(d) - Y_i(0)$ for each unit i , are not quantifiable and this is sometime referred to as *the fundamental problem of causal inference*. Instead, the potential outcomes framework focuses the inference problem on estimation of averages in the form of ATEs, and determines the conditions under which these can be identified validly from the data.

One option for ATE estimation would be to simply take mean outcomes for groups of units defined by treatment status and compare (i.e., in the binary case we could compare the mean outcome for treated units with the mean outcome for untreated units). However, a key feature of transport interventions is that they are rarely randomly assigned, and when unit characteristics influence both treatment assignment and outcome simultaneously, bias will ensue in ATE estimation based on naïve comparisons of group means. This implications of nonrandom assignment is illustrated in Fig. 1.

Note that under randomization the characteristics of units in the sample, denoted X , have no influence on the treatment received (i.e., on D). Consequently, outcomes are unconditionally independent of the treatment assignment mechanism (i.e., all units in the sample have an equal probability of being assigned to treatment), and a simple comparison of mean outcomes by treatment groups will yield valid inference about the ATE for the population. Under a nonrandomized assignment, the allocation of the treatment depends on characteristics X , which are themselves important in determining outcome Y . Consequently, simple comparisons of mean responses across different treatment groups will not in general reveal a causal effect. Under these conditions, we refer to X as *confounders* and describe the treatment effect estimation problem as *confounded*. A confounder, therefore, is simply a random variable

Figure 1 Directed acyclic graph of randomized and nonrandomized treatment assignment.

that influences the outcome of interest, but that is also important in determining (nonrandom) assignment to treatment. It is worth noting that *confounding* can arise dynamically, with past outcomes or treatments of units serving as baseline confounders (e.g., X can contain lagged values of D and Y).

Transport interventions are typically nonrandomly assigned, for example, because they are used to induce improvements in congested locations, in accessibility constrained locations, or in locations with poor economic performance. This implies that locations that receive transport interventions will tend to be in some sense different from those that do not. If this is the case, *confounding* is said to be present and this makes it hard to separate the effect of the treatment from other influences through simple comparisons based on treatment status alone. For ex post evaluation, the implication is that in order to obtain valid unbiased causal estimates of the ATE we need to somehow account for differences in confounding characteristics.

Broadly speaking there are two way of doing this. First, through model-based adjustment for confounding, in which differences between units in characteristics X , are measured and included within a model to obtain marginal causal effects (i.e., ATE net of confounding influences from X). Second, by developing models which exploit sources of exogenous variance to obtain causal estimates without explicit representation of X in the model. In the following two sections we consider each of these approaches in turn.

Ex Post Evaluation via Model-Based Adjustment for Confounding

A key insight of the potential outcomes approach is that to estimate the ATE we do not need to observe all potential outcomes, even under a nonrandom treatment assignment. Observed data are sufficient to conduct model-based adjustment for confounding as long as three key assumptions hold.

1. **Conditional independence:** The potential outcomes for unit i must be conditionally independent of the treatment assignment given a (sufficient) set of observed covariates X_i . For binary treatments this assumption is written $Y_i(0), Y_i(1) \perp D_i = 1 | X_i$, and for multivalued or continuous treatments $Y_i(d) \perp D_i = d | X_i$, for all d . This condition simply says that, if we can measure the X vector that influences nonrandom assignment in Fig. 1, then we can use this to adjust for bias in ATE estimation.
2. **Common support:** Conditional on covariates X , the probability of assignment to the treatment must be strictly positive in infinite samples. For binary treatments, the common support assumption is written as $0 < \Pr(I_1(D_i) = 1 | X_i = x) < 1, \forall x$. For multivalued or continuous treatments, we require common support by treatment status in the covariate distributions within some region of dose, $C \subseteq D$, say. A sufficient condition is that for any subset of C , $A \subseteq C$, then $\Pr(D_i \in A | X_i = x) > 0, \forall x$. The intuition behind the common support, or overlap, assumption is that if some sub-populations observed in X have zero probability of receiving (or not receiving) the treatment, then it does not make sense in these cases to talk of a treatment effect since the counterfactual does not exist in the observed data.
3. **Stable unit treatment value assumption (SUTVA):** The relationship between observed and potential outcomes must comply with the SUTVA, which requires that observed outcomes under a given treatment allocation must be equivalent to potential outcomes under that allocation. For binary treatments this implies that $Y_i = I_1(D_i)Y_i(1) + (1 - I_1(D_i))Y_i(0), \forall i = 1, \dots, n$; and for multivalued or continuous treatments SUTVA requires that $Y_i = I_d(D_i)Y_i(d), \forall d \in D, i = 1, \dots, n$. A key implication of the SUTVA is that the outcome for each unit should be independent of the treatment status of other units, or in other words, there should be no interference in treatment effects across units. SUTVA also implies that there are no different versions of the treatment. The no interference assumption is generally satisfied when the units are physically distinct and have no means of contact. Violations of the assumption can occur when proximity of units allows for contact and this presents a particular concern for transport applications.

The three assumptions defined above, which are together referred to as *strong ignorability*, provide the conditions for identification of causal effects from observational data. This can be demonstrated as follows. For binary treatments, the ATE can be derived as

$$\begin{aligned} \tau(1) &= E[Y_i(1)] - E[Y_i(0)] \\ &= E_X[E(Y_i(1)|X_i = x) - E(Y_i(0)|X_i = x)] \end{aligned}$$

$$\begin{aligned}
&= E_X[E(Y_i(1)|X_i = x, D_i = 1) - E(Y_i(0)|X_i = x, D_i = 0)] \\
&= E_X[E(Y_i|X_i = x, D_i = 1) - E(Y_i|X_i = x, D_i = 0)],
\end{aligned}$$

where, the equality of the second and third lines follows from conditional independence, the SUTVA allows the substitution of observed for potential outcomes to give line 4, and overlap ensures that the population ATE is estimable since there are units in both the treated and untreated groups. Thus, in place of unobservable $E[Y_i(1)]$ and $E[Y_i(0)]$, we are able to substitute conditional expectations of observable quantities.

Similarly, for continuous or multivalued treatments the Average Potential Outcome (APO), or *dose-response function*, under a given dose d is defined, $\mu(d) = E[Y_i(d)]$, and can be derived as,

$$\mu(d) = E[Y_i(d)] = E_X[E(Y_i(d)|X_i = x)] = E_X[E(Y_i(d)|X_i = x, D_i = d)] = E_X[E(Y_i|X_i = x, D_i = d)]$$

where the second equality follows from conditional independence, the third from the SUTVA, and the overlap assumption ensures that the APO is estimable since there are comparable units across treatment levels. Note that the ATE is the difference between APOs, that is, $\tau(d) = E[Y_i(d)] - E[Y_i(0)] = \mu(d) - \mu(0)$.

To proceed we need to estimate the relevant conditional expectations in the equations above. There are three approaches that are commonly used in the literature to do this: outcome regression (OR), propensity score (PS) models, and mixed or Doubly Robust (DR) models.

Outcome Regression

Outcome regression models can be used to estimate ATEs under nonrandom assignment. This can be achieved, for instance, via a Generalized Linear Model (GLM) or some parametric or semiparametric variant thereof. If the OR model, denoted $E[Y_i|D_i, X_i] = \psi^{-1}\{m(D_i, X_i, \beta)\}$ for known link function ψ , regression function $m(\cdot)$, and unknown parameter vector β ; is correctly specified for the mean response then the ATE can be consistently estimated in the binary case using

$$\hat{\tau}_{OR}(1) = \frac{1}{n} \sum_{i=1}^n [\psi^{-1}\{m(1, X_i, \hat{\beta})\} - \psi^{-1}\{m(0, X_i, \hat{\beta})\}]$$

And in the case of continuous or multivalued treatments using

$$\hat{\tau}_{OR}(d) = \frac{1}{n} \sum_{i=1}^n [\psi^{-1}\{m(d, X_i, \hat{\beta})\} - \psi^{-1}\{m(0, X_i, \hat{\beta})\}].$$

Note that covariate vector X is included in the regression models to adjust for confounding and thus to invoke conditional independence.

Propensity Score Methods

The propensity score (PS) is a random variable that measures the conditional probability of being assigned to some value of treatment given background confounding characteristics. For unit i we denote the PS by $\pi_i = \Pr(D|X_i, \alpha)$. As noted above, if observed covariates are sufficient to represent sources of confounding then they can be used to establish conditional independence between outcomes and treatment assignment. An important property of the PS is that conditional independence can be established conditional on the scalar PS rather than on the full covariate vector X . A key advantage in using the PS is that we avoid the need to condition on a potentially high dimensional covariate vector, and it is this dimension reducing property that allows for effective implementation of a number of flexible estimators for ATEs.

PS are not observed but are calculated by estimating the relationship between D and X using a regression model $E[D_i|X_i] = \psi^{-1}\{m(X_i, \alpha)\}$ for link function ψ , regression function $m(\cdot)$, and unknown parameter vector α . The estimated parameters of this model are then used to compute propensity scores, $\hat{\pi}_i = \hat{\pi}(D|X_i; \hat{\alpha})$. Once we have the estimated PS, they can be used to form a number of different nonparametric and semiparametric estimators via weighting, matching, stratification, blocking, and regression.

To illustrate, we will consider here one of the simplest PS-based estimators: the inverse PS weighting estimator. Under inverse PS weighting estimation of the ATE for binary treatments takes the form

$$\hat{\tau}(1) = \frac{1}{n} \sum_{i=1}^n \left[\frac{I_1(D_i) \cdot Y_i}{\hat{\pi}(D|X_i; \hat{\alpha})} - \frac{(1 - I_1(D_i)) \cdot Y_i}{1 - \hat{\pi}(D|X_i; \hat{\alpha})} \right],$$

and for continuous and multivalued treatments

$$\hat{\tau}(d) = \frac{1}{n} \sum_{i=1}^n \left[\frac{I_d(D_i) \cdot Y_i}{\hat{\pi}(D|X_i; \hat{\alpha})} - \frac{(1 - I_d(D_i)) \cdot Y_i}{1 - \hat{\pi}(D|X_i; \hat{\alpha})} \right],$$

where $I_1(D_i)$ and $I_d(D_i)$ are indicator for receipt of treatment.

The principle of IPW estimation is creation of a *pseudo-sample* to simulate random assignment by using the conditional probabilities to mimic the sample representation of units that would occur under randomization. The intuition is as follows. We know that under a random assignment the probability of assignment to treatment is uniform across unit in the sample. By measuring how baseline characteristics cause deviations from this uniform probability, we can weight units to effectively alter their representation in the sample such that we get back to an assignment, that is, for all intents and purposes, *as good as random*. Note that the consistency of ATE estimation under this approach relies on the PS model being correctly specified (i.e., the estimated PS must provide an accurate measure of the conditional probability of assignment to treatment).

Doubly Robust Estimation

Doubly robust (DR) estimators combine both an OR model and a PS model such that valid causal estimates of ATEs can be obtained when either the OR or PS model is correctly specified, but we do not require both to be correct. It is therefore useful when the analyst can formulate two models for evaluation but is unsure a-priori as to which best represents the link between treatment assignment and outcome.

DR estimation is typically achieved by weighting or augmenting the OR model with inverse PS covariates. For example, a DR Augmented Outcome Regression (AOR) model has the form

$$E[Y_i | D_i, X_i \hat{\kappa}(D_i, X_i)] = \Psi^{-1}\{m(D_i, X_i, \hat{\kappa}(D_i, X_i), \xi)\}$$

where $\hat{\kappa}(D_i, X_i)$ is a vector of inverse PS covariates estimated from observed data. In the case of binary treatments

$$\hat{\kappa}(D_i, X_i) = \frac{I_1(D_i)}{\hat{\pi}(D|X_i; \hat{\alpha})} + \frac{(1 - I_1(D_i))}{1 - \hat{\pi}(D|X_i; \hat{\alpha})},$$

and for multivalued and continuous treatments a discretization of the treatment into Q strata is imposed, $q = (1, \dots, Q)$, and

$$\hat{\kappa}(D_i, X_i) = \sum_{q=1}^Q \frac{I_q(D_i)}{\hat{\pi}(D|X_i; \hat{\alpha})}.$$

The ATEs are estimated as for binary treatments as

$$\hat{\tau}_{DR}(1) = \frac{1}{n} \sum_{i=1}^n [\Psi^{-1}\{m(1, X_i, \hat{\kappa}(D_i, X_i), \hat{\xi})\} - \Psi^{-1}\{m(0, X_i, \hat{\kappa}(D_i, X_i), \hat{\xi})\}],$$

and in the case of continuous or multivalued treatments as

$$\hat{\tau}_{DR}(d) = \frac{1}{n} \sum_{i=1}^n [\Psi^{-1}\{m(d, X_i, \hat{\kappa}(D_i, X_i), \hat{\xi})\} - \Psi^{-1}\{m(0, X_i, \hat{\kappa}(D_i, X_i), \hat{\xi})\}],$$

The key feature of DR estimators is that APO and ATE estimates are consistent and asymptotically normal when either the OR or PS model are correctly specified, but we do not require both models to be correct. Thus, the analyst effectively has two chances at obtaining valid causal inference. Of course, if the measure of X available in the observed data is insufficient to guarantee conditional independence, then both the OR and PS models will fail and DR estimation will not improve matters.

Ex Post Evaluation Under a Nonignorable Treatment Assignment

The validity of the evaluation methods discussed above requires us to maintain that *strong ignorability* holds (see section Ex Post Evaluation via Model-Based Adjustment for Confounding). In practice, this is often untenable, either because there are insufficient measured covariates to establish conditional independent, or because other sources of endogeneity (e.g., reverse causality or measurement error) are at play inhibiting a causal interpretation of the data.

There are a number of popular estimators that are used in this setting to obtain causal estimates of the ATE. Some use additional variables (instruments) to extract exogenous variation in treatments, while others exploit quasi-experimental conditions for identification. Here we briefly review three of the most commonly used approaches in economic evaluation: instrumental variables (IV), difference-in-differences (DID), and regression discontinuity designs (RDD).

Instrumental Variables

The IV estimator is well known and widely used in empirical studies across diverse fields of study. The key principles of IV estimation is to use exogenous variation, in the form of instruments, to nullify the bias due to confounding, measurement error, or reverse causality. The logic of the IV method is as follows:

1. Find a set of instruments which are exogenous to the outcome but highly correlated with the treatment.
2. Use the instruments to enforce orthogonality between the error term and an instrument transformed design matrix.

Figure 2 Relationships in instrumental variables estimation.

The relationships assumed in IV estimation are shown graphically in Fig. 2 in the context of the linear regression model $y = D\tau + u$ with instrument matrix Z .

The defining characteristics of the IV model are that changes in z are associated with changes in d , but do not lead to changes in y other than through d . Thus, z is causally associated with d but *definitely* not with u . A common method used to obtain IV estimates is two-stage Least Squares (2SLS), which comprises two steps:

1. Regress each column of D on the instrument matrix Z .
2. Regress y on the predicted values from the first stage.

IV can be used to establish causal effects under a nonignorable treatment assignment and is particularly useful when bidirectionality causality is present. However, it is crucial that the two key assumptions of exogeneity and relevance are met, and in practice such instruments can be hard to find. When instruments are only weakly correlated with the endogenous regressors, or when the instruments themselves are correlated with the error term, IV estimation can produce biased and inconsistent estimates. This problem is further compounded by the fact that the available diagnostic statistics do not provide a full proof means for detecting an inadequate instrument specification.

When panel data are available, but exogenous instruments are not, one commonly adopted route forward is to use the dynamic panel Generalized Method of Moments (GMM) estimator for panel data. Dynamic GMM applies differencing to remove the unobserved individual effects and uses the time series nature of the data to derive a set of instruments from lagged levels which are assumed correlated with the differenced covariates but orthogonal to the errors. A set of moment conditions can then be defined and solved within a GMM framework which will be satisfied at the true value of the parameters to be estimated.

Difference-in Differences

Differences-in-differences is a “before and after” treatment effect estimation approach that is applicable when the effect of treatment on units can be represented as a binary variable (i.e., “treated” or “control”). It can reveal impacts associated with exposure to an intervention relative to nonexposure (control), but it cannot tell us about impacts by scale or “dose” of intervention.

A problem in identifying treatment effects via OR, PS, or DR models is that there may be *unobserved* differences between the treated and untreated units which affect outcomes and are also influential in treatment assignment (i.e., unobserved confounders). In addition, there may be temporal trends that affect the outcome variable due to events that are unrelated to the treatment.

The DID estimator addresses such potential sources of bias by using information for both treated and control groups in both pre and post treatment periods. The DID estimator approximates the expression

$$\tau_{DID} = \{E[Y_i(1)|D_i = 1] - E[Y_i(1)|D_i = 0]\} - \{E[Y_i(0)|D_i = 1] - E[Y_i(0)|D_i = 0]\}.$$

The “double-differencing” of the DID estimator removes two potential sources of bias. Firstly, it eliminates biases in second period comparisons between the treated and control groups that could arise from time invariant characteristics. Secondly, it corrects for time varying biases in comparisons over time for the treated group that could be attributable to time trends unrelated to the treatment.

An estimate of τ_{DID} can be obtained via linear regression. For instance, we can estimate the model

$$Y_{i,t} = \mu + X'_{i,t}\beta + \alpha D_{i,t} + \delta^*t + \tau D_{i,1} + \varepsilon_{i,t}$$

for units of observation i , $i = (1, \dots, n)$ in binary time periods $t \in \{0, 1\}$, with $t = 0$ representing the pretreatment period and $t = 1$ the posttreatment period. In this model $D_{i,t}$ is the treatment indicator variable such that $D_{i,t} = 1$, if unit i has been exposed to the treatment prior to period t and $D_{i,t} = 0$ otherwise, δ is a time specific component, and $\varepsilon_{i,t}$ is a potentially autoregressive error with mean zero in each time period. The effect of the treatment is captured by the parameter τ .

It is important to note two potential limitations with the DID approach. First, it relies on the strong identifying assumption that the average outcomes for the treated and control groups would have followed parallel paths over time in the absence of the treatment. Adding covariates to the linear DID regression (i.e., X) can help in satisfying the parallel trend assumption because it is then assumed to hold conditional on those covariates, thus accommodating heterogeneity in outcome dynamics between the two groups.

Second, the model is sensitive to error specification, and in particular, it has been shown that the existence of correlation within groups or over time periods can adversely affect the performance of the DID estimator.

Regression Discontinuity Designs

RDD methods can estimate ATEs under nonignorability when a given covariate, referred to as the forcing or running variable, partly or completely determines assignment to the treatment. Under a so-called “sharp” RDD design, the conditional probability of receiving the treatment is of size one at some given threshold of the forcing variable, while under a “fuzzy” design the probability change at the threshold is less than one. The RDD method exploits this discontinuity in treatment assignment to study the conditional distribution of the outcome either side of the threshold of the forcing variable. A discontinuity in outcome is interpreted as evidence of a causal effect of the treatment.

For illustration, we will consider here identification under a sharp RDD design in which treatment assignment is a deterministic function of the forcing variable, which we denote by T . The treatment status of unit i is given by

$$D_i = 1 [T_i \geq c]$$

where $1 [T_i \geq c]$ is an indicator function that takes a value of one if the statement in brackets is true or zero otherwise. We seek to estimate the expression

$$\tau_{SRD} = E[Y_i(1) - Y_i(0)|T_i = c] = E[Y_i(1)|T_i = c] - E[Y_i(0)|T_i = c]$$

which is equivalent to the population ATE, if the treatment effect is constant. We cannot observe both expectations because we have unobserved potential outcomes. Instead, we assume continuity of the expectations in T such that

$$E[Y_i(0)|T_i = c] = \lim_{t \uparrow c} E[Y_i(0)|T_i = t] = \lim_{t \uparrow c} E[Y_i|T_i = t]$$

Implying that

$$\tau_{SRD} = \lim_{t \downarrow c} E[Y_i|T_i = t] - \lim_{t \uparrow c} E[Y_i|T_i = t].$$

The ATE we estimate via the sharp RDD design is the difference in the conditional expectation of the outcome either side of the discontinuity. A valid RDD design will provide consistent causal estimates of the ATE without the need to condition on baseline covariates, but it can however be useful to include them anyway to reduce the sampling variability of the estimator and improve precision.

Summary

In this chapter, we have reviewed methods that seek to draw causal inference from observed data and have indicated how they can be applied to undertake ex post evaluation of transport projects. We argue that a causal inference framework, based on potential outcomes, is highly suitable for ex post evaluation because it is specifically designed for instances in which “treatments” are nonrandomly assigned and experimentation is not possible; circumstances that characterize the allocation of transport interventions.

While the methods reviewed here can be used to successfully derive inference about the causal effects of transport interventions, there are several challenges that should be acknowledged.

First, is that for some of the methods, especially those reviewed in section Ex Post Evaluation via Model-Based Adjustment for Confounding, all potential sources of confounding must be measured to obtain valid inference. This onerous data requirement must be met to satisfy the so-called “selection on observables,” or conditional independence, assumption. In practice, we typically face situations in which confounders are unobserved, or measured with error, and it is then difficult to defend methods that require conditional independence to hold. The problem is exacerbated by the fact that there are no reliable diagnostic procedures to comprehensively test for violation of this key assumption.

Second, there are other methods, including all of those reviewed in section five, which perhaps require less data but instead impose stringent identifying assumptions. In the case of IV estimation instruments must be relevant and exogenous, for DID models a parallel trend must hold, while continuity of outcomes and non-manipulation of the treatment threshold must hold for valid identification under RDD estimation. It can be hard to establish empirically whether these assumptions hold in practice and again diagnostics are not always clear cut.

Finally, another key challenge for ex post evaluation relates to the SUTVA condition mentioned above, which applies to all methods reviewed in this chapter. A key implication of the SUTVA is that the outcome for each unit must be independent of the treatment status of other units, or in other words, there should be no “interference” in treatment effects between units. In evaluations based on spatial data, the assumption of no interference is often satisfied naturally when the units are physically distinct and have no means of contact. But violations of the assumption can occur when proximity of units allows for contact or network-based interactions are present. This presents a particular concern for evaluation of transport interventions, which are assigned within networks in which improvements on one link or node can affect outcomes for other spatiotemporal units throughout the network.

Introduction

There exists now a large body of theoretical and empirical literature that shows that transport costs for goods and people affect firm location in multifaceted ways and that changes in transport cost have important implications for the reorganization of firms across space. This article first reviews some of the main theoretical approaches to explain firm location and the role of transport cost. This is followed by a review of empirical studies on transport cost and firm location distinguishing how transport costs are measured, which geographical level is the unit of analysis, and which type of firms and transport infrastructure is analyzed. Transportation technology has changed profoundly over the course of history and with it transport costs and the location of firms. New developments will certainly also influence the location patterns of firms. Extent and direction of changes will, however, depend among other things also on the interactions between changes in transport cost for goods and people, the cost of exchanging complex knowledge and information, and the opportunity cost of time.

Theoretical Approaches to Explain Firm Location

Economists and geographers have long been concerned about the influence of transport cost on the location of firms and the resulting spatial distribution of economic activity. Transport plays a crucial role in the overcoming of the frictions of distance. It enables spatial interaction and economic transactions over distance.

Early models of firm location such as the models by [Von Thünen \(1826\)](#) and [Weber \(1929\)](#) have been centered on transport costs and location. Von Thünen focused on agricultural location and the transport of agricultural produce to a central market. In his model, differences in transport costs to bring the produce to the central market determine what is produced at different distances from the market. Falling transport costs allow production of a particular produce further away from the market center. In the industrial location model of Weber, both transport costs for raw materials and the final good are taken into account. Weber assumed that raw materials are allocated across space but buyers are located also at the market center. Firms search for the least-cost location that minimizes the transport cost for raw materials and that allows for the lowest delivered cost of the final good to the market center. Depending on the transport costs involved in the transportation of the inputs and outputs relatively, the least-cost location is either near the raw material source or at the market center. However, the role of input and output transportation costs is not independent of the production technology adopted as firms can adapt to changes in transportation costs by changing the relative proportions of inputs as well as the characteristics of outputs. Other models have centered on the market area of firms. [Lösch \(1954\)](#), for example, developed a model where buyers are distributed evenly over a market area.

Starting with the work of [Krugman \(1991\)](#), New Economic Geography (NEG) regional models center on increasing returns to scale and transport costs. NEG approaches concentrate on the role of market-size effects and forward and backward linkages giving rise to pecuniary externalities (centripetal forces) that foster geographical concentration, on the one side, and the opposing force of competition in product and factor markets (centrifugal forces) working against such concentration. These models point to complex mechanisms by which transport costs affect firm location. With high transport costs, firms are distributed evenly across regions because of the need to be close to customers to keep transport costs of final goods low. The decrease of interregional transport costs together with increasing returns sets in a process of concentration in core regions as transport cost reductions lower the cost of firms to sell output to customers at greater distance. This extends the market area and facilitates agglomeration in core regions. Greater market size of core regions allows for higher productivity. Firms in core regions thus can pay higher wages that attract workers from peripheral regions. Core regions also have a higher diversity of goods that increases consumer's utility, increasing further the

attractiveness of core regions to labor. The increase in labor raises demand in the goods market that attracts again other firms. In this case, a fall in transport costs leads to the weakening of centrifugal forces and encourages agglomeration in core regions. This, however, also raises factor competition and consequently the price of labor and land.

Further reductions in transport costs could then set in again a process of dispersion as lower transport costs open up new sites for production where firms can take advantage of cheaper labor and land. Transport cost reductions thus change the trade-off between different location factors and consequently the distribution of firms between core and peripheral areas. Whether transport costs reductions are agglomerative or dispersive depends on several factors. Firms that have high relative transport costs may respond to transport cost reduction by concentrating, but firms with lower transport costs may disperse to more peripheral locations to take advantage of lower factor costs. This means that transport cost reductions can in theory reduce but also increase regional inequalities due to the different responses of firms in changing the location of their activities over space (Holl, 2007). NEG points out this potential ambiguity in the impact of transport cost reductions on firm location.

Within the NEG framework, there have also been studies that have shown that interregional and intraregional transportation costs have different effects on firm location. Reducing intraregional transport costs generally leads to attracting firms to that region. However, reductions of interregional transportation costs in a poor region can induce relocation of firms away from this region. Other extensions introduce commuting costs and how together with the cost to transport goods they influence firm location.

Transport costs also play a prominent role in models of urban economics and the related firm location within urban and metropolitan areas. In the classical monocentric city models of Alonso, Mills, and Muth firms are located at the city center close to central rail hubs and ports (Mieszkowski and Mills, 1993). These were the locations that minimized firms' transportation costs before the introduction of cars and trucks, as they were the most accessible locations from the point of view of the transportation of goods as well as people. Regarding the latter, spatial differences in commuting costs of workers are compensated through the housing market where land rents adjust as a function of distance to the center.

Transport cost reductions due to innovations and improvements in transportation can lead to urban employment decentralization. Historically, cheaper and better transportation such as the introduction of cars and trucks and the construction of highways have freed firms from central city locations. By not relying on the central transportation hub for the shipping of goods, firm could find it advantageous moving to suburban locations in search of lower land costs and labor cost savings. Thus, the reduction in transportation cost for goods can promote changes also in the urban spatial structure.

In addition, once firms are distributed within the urban area and no longer concentrated in the center, compensation for differences in commuting costs can also happen through wages where firms in locations that are difficult to access have to pay a wage premium for higher commuting costs. Wages thus constitute another source through which transport costs influence firm location.

Traditional location theory deals with the firm as a single unit, but the typical large modern firm is organized in multiple units, where, for example, production facilities and different business administration offices are often separated in space. This spatial separation of different activities of the firm has been facilitated by the developments in information and communication technology (ICT) that have allowed reducing the cost of information transmission. Standard production activities and tasks have been decentralized and moved to more peripheral locations to take advantage of lower land and labor costs, while management tasks that require the exchange of tacit knowledge and complex information tend to concentrate in central business districts where face-to-face contacts are facilitated. Thus, transport costs influence the location behavior of firms depending on their functional specialization.

Empirical Studies on the Role of Transport Costs for Firm Location

A firm's location is the result of a consideration of multiple factors. There is a very broad literature that has analyzed the importance of different location determinants, but only some of them have examined explicitly the role of transport costs for firm location.

Empirical approaches to study the role of transport costs for firm location have broadly followed two main approaches: (1) survey approaches, and (2) econometric studies using firm location data (Holl, 2006, 2007).

Survey approaches investigate the role of transport among other factors in firms' location decision from the viewpoint of the managers making the choice. Two types of survey approaches can be distinguished. First are those studies that inquire about the determinants behind the firms' actual location choice. Such surveys involve a series of questions relating to firm characteristics, the actual location choice, and different location factors, including how transport influenced the choice. Entrepreneurs are asked to assess the factors that determined their choice of location usually on a Likert scale. These studies show that transport cost consideration do influence firms' location choice. Although many firms perceive transport considerations as very important or at least as important in their location choice, there are also other factors that influence the location decision. For example, the literature has documented home bias in location choices that can be related to personal preferences of entrepreneurs and existing networks and relationships of trust and local knowledge that facilitate business relationships and that are costly to replicate outside the home location. Other relevant factors are usually local amenities and quality-of-life issues or access to skilled labor and labor costs. Findings of survey studies show that lower transport costs relax location constraints, allowing firms to examine a wider range of locations. Second, there have also been survey studies that have inquired about how specific transportation improvements have impacted on firms in different locations. Firms in the vicinity of new transportation improvements are often reported to have benefited in terms of reduced input ordering times, improved output delivery, and customer service.

Survey studies refer to a specific research context and provide information about entrepreneurs' perceptions about location factors. A different approach is to ask how transport costs make a location more or less attractive for firm location compared to other locations. In this regard, transport has been considered explicitly in a range of econometric firm location studies usually framed within the discrete choice approach. Four empirical issues distinguish the studies in this strand from each other: (1) how transport costs are measured, (2) which geographical level is the unit of analysis, (3) which type of firms, and (4) which transport infrastructure is analyzed.

The Measurement of Transport Cost

Measuring transport costs is challenging. The transport costs that influence firm location include both the transport cost for goods and people and both monetary and nonmonetary costs. Data on the actual transport costs incurred by firms are rarely available. Even if there is information on firms' direct transportation expenditure, for example, from balance sheet information, the full distance-related costs are not observable directly. Part of the full distance-related transportation costs that a firm faces in a given location are also embedded in input and output prices and part of it is reflected in the opportunity cost of time for goods as well as for people. Such data constraints mean that empirical studies in general have reverted to a range of proxies for transport costs and their spatial variations.

In the trade literature, a common approach is to use distances between trading partners to estimate a gravity equation in order to derive an approximation of transport costs from the parameter estimates, but these measures can also capture other factors beyond transport costs, that is, cultural and institutional differences. Nevertheless, even with additional controls, these studies indicate that most shipments occur over relatively short distances and flows decline relatively rapidly with increasing distance, reflecting the increasing transport costs. Some studies have also adjusted distances with the quality of infrastructure. This shows that trade flows not only decline with increasing distance, but that a deterioration of infrastructure raises transport costs as well and also reduces trade volumes. Fewer studies have used commodity flow data to calculate *ad valorem* transport costs, as the availability of such data is generally limited (as a notable example, see [Behrens et al., 2018](#)).

As a result of the difficulty to obtain consistent estimates for firms' generalized transport costs, most studies in the firm location literature have focused on the role of transport infrastructure. After all, firms' transport costs arise from the need of moving of inputs and outputs and from personal travel, and this requires transportation infrastructure. Transport costs are hence closely related to availability and quality of different transportation infrastructures. Nevertheless, a limitation of infrastructure-based measures is that they do not provide goods- or industry-specific variations ([Behrens et al., 2018](#)). Yet, the importance of transport costs will vary with the specific characteristics and values of the goods that need to be transported or services that need to be provided over distance.

Among firm location studies, some have used indicators of transport infrastructure endowment in the region where the firm is located such as kilometers of rail lines, kilometers of highways, and number of airports or ports. Other studies have proxied transport costs with different accessibility indicators. In practice, a wide range of accessibility measures have been used such as network access measure (i.e., distance to the nearest highway, railway, port, or airport), travel time measure, and potential accessibility measures or market potential measures. Accessibility indicators measure the relative position of the location within the transport network and take into account the network character of the infrastructure.

Geographical Level of Analysis

Regarding the spatial scale of firm location choices, they have been studied at different levels ranging from the international level (i.e., looking at foreign direct investment decisions), to the interregional level and the intraregional level. Related to the latter, there have been specifically a range of studies that have looked at urban and metropolitan areas and how transport costs affect firm location within those areas. Transport cost reductions show different impacts according to the spatial scale of analysis, that is, intraregional versus intraregional transport costs and transport costs within and between urban areas. The question of the spatial scale of analysis is of course not unrelated to the type of firm and the type of transportation infrastructure whose influence on firm location is studied, that is, air transport is rather taken into account in studies of international firm location, while subways or urban railways are studied naturally at the urban and metropolitan level.

Types of Firms

Transport costs depend on the specific firm's product or service characteristics and the production and distribution systems or organization that is implemented in the company. Clearly, some firms and consequently sectors will be more dependent on transportation and they will therefore also be more sensitive in their location choice to transport cost. Research for the United States has shown that vehicle-intensive industries experience greater productivity growth when roads are improved ([Fernald, 1999](#)). Thus, transport-intensive industries are also more likely to be influenced more strongly in their location choice by roads ([Holl and Mariotti, 2018](#); [Gibbons et al., 2019](#)).

Most research on the role of transport costs on firm location has focused on the manufacturing sector. However, there are also important differences within manufacturing. For example, some research has shown that durable goods producers react differently to transport infrastructure improvements than perishable goods producers ([Rothenberg, 2013](#)). High transport costs for perishable goods mean that they need to be produced close to consumers and firms are hence dispersed. In contrast, durable goods have lower

transport costs and their production is more concentrated. The evidence shows that with road improvements that further reduce transport costs, the latter firms disperse to locations with lower land and labor costs, but still in the vicinity of the large urban agglomerations. Along the product life cycle, the benefits from locating in urban locations versus more peripheral locations also change. In the early stages, the firm finds greater learning opportunities in more diversified urban areas. The firms' needs for complex information and knowledge transmitted through face-to-face contacts play a greater role. However, when the production process becomes standardized firms have an incentive to relocate to specialized cities. Thus, start-ups and relocating firms are attracted by different location characteristics and there is also some empirical evidence that manufacturing plants that relocate are more strongly attracted by the proximity to highways compared to start-ups (Holl, 2004a).

Fewer studies have looked at the service sector. However, the service sector is now the most important sector in developed economies. For those firms, the role of transport stems mainly from the need of personal travel. For corporate office and headquarter location choice, the cost, time, and reliability of transportation for executive travel is an important factor. Face-to-face communication with clients and other businesses are crucial and thus they tend to locate in central business districts. It is thus also likely that front office and back office services show different location patterns and are influenced differently by transport cost considerations, as the latter process standardized information and need less face-to-face contacts. However, to date there is very little empirical evidence beyond specific case studies on firm locations that distinguishes between front office and back office services and how transport costs influences differ. Nevertheless, the limited empirical evidence also indicates that back offices are attracted by the proximity to highways, while front office by city center locations with good accessibility. This reflects that different types of transport cost considerations come into play for the different location choices.

Types of Transport Infrastructure

Regarding the type of transportation infrastructure, roads are in general the most important type. Roads constitute the bulk of infrastructure capital and the backbone of transportation systems and the majority of passenger and freight transportation is carried on roads in most countries. It is thus not surprising that most firm location studies have also focused on roads and specifically on highways. These studies have shown that there is a tendency of firms to move closer to highways in order to benefit from improved accessibility and hence lower transport costs. Most studies on the economic impacts of road transport infrastructure investment have found positive growth effects with higher density of firms and greater economic activity in general. However, new roads not only contribute to economic growth but also, as shown by NEG, cause the reorganization of economic activity (Redding and Turner, 2015). While highways increase the attractiveness of locations for firm location in their vicinity, this can also come at the detriment of other areas. There is empirical evidence that shows that highways attract firms into their corridors but at the same time reduce the attractiveness of locations adjacent and beyond their corridors (Chandra and Thompson, 2000; Holl, 2004b; Gibbons et al., 2019). Within the urban and metropolitan context there are furthermore studies that have shown that new highways have led to suburbanization (Baum-Snow, 2007; Garcia-Lopez et al., 2015). Thus, highways can also negatively affect city center locations. It has not only been people but also certain types of firms that have been induced to move to urban fringes with road improvements that lowered transport costs: especially manufacturing jobs and standardized office jobs. Furthermore, there is also some limited evidence that new highway connections can hurt peripheral regions that are crossed by the new highways while leading to greater concentration of firms in core regions.

Rail accounts for a small fraction of goods movements in most countries. Still, rail can play a role for the location of firms that require bulky commodities that need to be transported over medium to long distances. In the urban context, there is some evidence that access to light rail influences office firm location and retail firm location and that the expansion of subway systems has also led to the dispersion of economic activity, similar to the findings on urban highways. In several countries, recent years have seen a shift from infrastructure investment in roads to high-speed rail (HSR). While HSR is usually not used for the transportation of goods, it can affect the location of service sector firms and particularly business service firms and also headquarter location. Most studies conclude that new HSR stations increase the attractiveness of cities but it also generates disadvantages for cities in-between that are not served. The evidence for intermediate stops in smaller cities is generally also positive in terms of attracting new firms.

Studies concerned with the impact of rail on firm location face the challenge that accesses to not only such infrastructure counts but also the level of service that is provided. The same challenge faces studies that are concerned with the impacts of ports or airports for firm location. Ports and airports play a potentially important role particularly for long distance and international transport. Access to these facilities influences global trade patterns. With the ongoing globalization process, fast and reliable long-distance transport has also become ever more important. In several time sensitive sectors, airfreight is part of logistics strategies and thus access to air terminals can be an important location factor for global business. Some studies have also documented the importance of airports, and in particular the availability of nonstop intercontinental flights, for headquarter location choice (Bel and Fageda, 2008). Regarding ports, there is some evidence that in countries where domestic transport costs are still very high, such as for example in African countries, distance to ports matters for city growth (Storeygard, 2016).

Trends and a Brief Look Forward

Transportation technology has changed profoundly over the course of history and each dominant form of transportation has had its own imprint on the spatial location and organization of economic activity in general and firms in particular (Redding and Turner,

2015). The introduction, for example, of railways, cars and trucks, containerization, or air transportation has contributed to substantial reductions in transportation cost over time. Recent decades have also witnessed important improvements in transportation. Moreover, developments in ICT have enabled economic relations over greater geographical distances.

This has led some authors to suggest that the role of transport cost for firm location is declining. But the role of transport could also have become more important. Reductions in transport costs together with the advances in ICT have not only facilitated economic relations over greater distances but also led to important changes in industrial organization. Modern production and distribution systems have become more transport dependent with a rise in “just-in-time” (JIT) production and distribution, vertical disintegration and outsourcing, and globalization (McCann and Shefer, 2004; Holl, 2006).

Regarding inventory holdings, for example, the optimal level of inventories held within the production plant depends on transport costs, but also the speed, and reliability of transportation. There is evidence that when transportation systems are improved and transport costs decline, firms are reducing traditional inventory holdings, moving toward JIT and mobile inventories. Thus, for firms there is a clear trade-off between transport cost and inventory costs. With the rising importance of the factor time, reductions in the unit cost of transport can actually lead to higher total transport costs and a rise in total logistics costs (McCann and Shefer, 2004). In this context, the rising importance of the time cost of transportation can make transport considerations more important for firm location decisions.

Transport costs have declined primarily as far as the movement of goods is concerned, but the transport costs for people remain important, especially in terms of the opportunity cost of time, not only for the commuting of workers but also importantly in service provision and for face-to-face meetings (Glaeser and Kohlhase, 2004). With rising economic development, the opportunity cost of time is also rising. Thus, it is important to consider a broad notion of transport cost that includes the full opportunity costs of time. Moreover, in modern knowledge economies, the moving of goods is becoming relatively less important compared to the transmission and exchange of knowledge and complex information. Despite of the developments in ICT this is still strongly dependent on personal face-to-face contact, especially when it comes to tacit knowledge and highly complex information. This means that the relative relevance of different spatial transactions is changing and a broader notion of transport cost should also incorporate the costs for the transmission of information and knowledge.

Present day technological developments in the field of transportation such as the transition to autonomous vehicles have the potential to reduce traveling and transportation costs because the time used in traveling can be used otherwise. For firms it can mean that the time spent of workers traveling can be used more productively thus reducing their transportation costs and consequently increasing the accessibility of a given firm location. For example, in the road transport sector, personnel expenditure—mainly the driver costs—can account of up to over 70% of the total cost, especially in high wage countries.

As with transport innovation in the past, new transport technologies will certainly also influence the location patterns of firms, but a priori it is not clear if new innovation in transportation will stimulate a more decentralized pattern of firm location or if they will further strengthen spatial concentration. This will depend not only on the changes in transport costs and times, but also on advances in ICT, and the need for face-to-face meetings for knowledge exchange. In any case, it is likely that different changes in location patterns happen at different geographical scales and in different types of firms and economic sectors.

Autonomous vehicles have furthermore the potential to free up urban space from parking for alternative developments and to change the spatial structure of cities by making locations at the urban periphery better accessible as well as urban locations not served by public transport services. This can make new locations attractive for firm location. Finally, transport costs and firm location will also be influenced by public policies regarding air pollution and advancements in energy transition and the development of alternative fuel vehicles.

Concluding Remarks

Firm location is an important topic. Attracting new firms is an important source of concern for policy-makers at the city level, the regional level, as well as the national level. The capacity to attract firms and to keep the existing ones is an important determinant of future growth and competitiveness. New transport technology and investment in transportation infrastructure reduce the transport cost of goods and people and change the relative location advantages and consequently lead to the spatial reorganization of firms. The available empirical evidence suggests that reductions of transport costs can lead to a more dispersed pattern of firm location within metropolitan areas but they can also lead to greater concentration of certain sectors in core regions and to greater regional specialization.

It is important to bear in mind that the effect of transport costs on firm location should not be considered in isolation. Firm location is determined in equilibrium also with land rents and wages and transport costs influence both and depend itself on input–output linkages and production and distribution decisions. Modern production and distribution technologies are increasingly time-sensitive and, in this new scenario, rather than transport costs per se, what matters more are total logistics costs. Moreover, in a modern knowledge economy, the weight is shifting from the cost to transport goods to the cost of acquisition and transmission of complex information and knowledge.

The demand for transport derives from the need of spatial interaction of economic agents. Any changes in the location of firms will also impact transport demand. Thus, a better understanding of how transport affects firm location is also essential for predicting future transport demand and travel flows. Understanding the relationships between transport and location of firms is hence critical for tackling the challenges for sustainable transport solutions, especially in urban and metropolitan areas.

Introduction

Commuting implies the need to spend time that could have been used in a more productive way traveling from home to work and vice versa. It is therefore tempting to regard it primarily as a burden for which workers require compensation. This aspect is emphasized in the monocentric model, which focuses on the connection between commuting and housing consumption around employment centers. The labor market implied by this model is an extremely simple one, and more realistic models in which labor and housing markets are imperfect and jobs and workers heterogeneous offer important complementary insights into the value of separating employment and residential locations in dense urban areas. Lower commuting costs provide more space for exploiting agglomeration benefits while offering workers the possibility to combine working at highly productive locations with living in attractive residential areas. Dense urban labor markets allow for assortative matching of workers and jobs, resulting in higher productivity and wages. With overlapping local labor markets the immediate response to labor demand shocks may be an adjustment in the incoming and outgoing commuting flows through which the shock expands over space. In many respects, commuting thus plays a useful role in the functioning of urban and regional labor markets. This conclusion is entirely consistent with the fact that workers dislike long commutes and require significant compensation for accepting them.

Insights From the Monocentric Model

The Muth Condition

The monocentric model is the workhorse of urban economic analysis. It describes the location and housing choices of workers employed in a single center located on a featureless plain. The central issue of the model is that housing requires land, while workers dislike commuting. All workers would therefore like to live close to the employment center, but there is clearly not enough space to realize this. It is therefore inevitable that for most workers residential and work locations are spatially separated. The model elaborates on this issue, and therefore on the determination of commutes.

The classic treatment of worker location choice in the monocentric model assumes that workers maximize a utility function, $u(h, c)$ with h denoting housing (lot size, or housing services) and c other consumption, subject to a budget constraint: $p(x)h + c = \gamma - tx$, where $p(x)$ denotes the price of housing at location x , γ is income and t commuting cost per unit of distance.^a Location x is measured as the distance to the CBD. Since the employment center is—by assumption—located on a featureless plain, this distance is the only thing that matters to the worker. This is just the standard two good model of elementary microeconomics with two elements added: the price of one commodity, housing, depends on its location, as does the net income $\gamma - tx$ of the worker.

^a Note that the price of other consumption has been scaled at 1.

Note that in this simple version of the model time costs of commuting is not made explicit and commuting time does not directly affect utility.

The choice variables are the amounts consumed of housing and other goods and the location. First order conditions with respect to the first two variables are standard, but the third one—which is known as the [Muth \(1969\)](#) condition, is specific for this model:

$$\frac{\partial p}{\partial x} = -\frac{t}{h(x)}$$

With a homogeneous population of workers, this condition determines the curvature of the price of housing as a function of the distance to the center. It suggests a strong relationship between house prices on the one hand and housing consumption and commuting costs on the other. More specifically, commuting cost is a determining factor of the spatial pattern of house prices and of the density of housing. With high commuting costs, house prices decline sharply with distance from the employment center. Since house prices determine land prices, this implies that land prices in the employment center will be a steeply increasing function of the number of jobs in the center. This may impose limits on the size of such centers. With low commuting costs it is easier to give a large number of workers access to decent living space without land prices in the center getting extremely large.

Transportation Cost

Muth's condition suggests that high transportation costs impose important limits on the size of urban areas. Lowering these costs mitigates this constraint and can lead to larger cities with more housing consumption. Of course, commutes are also longer in such areas, but the important point is that the burden of commuting is, nevertheless, eased. There is indeed abundant evidence that lower transportation costs lead to expanding urban areas. For instance, suburbanization has been facilitated by the Philadelphia street car ([LeRoy and Sonstelie, 1983](#)), the London underground ([Heblich et al., 2018](#)) and 20th century highway networks ([Baum-Snow, 2007](#)). Recently the point has also been emphasized that lower commuting costs provide better possibilities for separating employment and work locations, which offers better possibilities for the realization of agglomeration economies. After the introduction of the London underground the center specialized rapidly in production activities, while workers choose to live in the quieter and less expensive outskirts of the city. At the same time, the lower population density may imply a loss of agglomeration benefits in consumption.

Heterogeneous Workers

With heterogeneous workers the Muth condition describes the slope of the bid rent function, while the actual house price function is the envelope of these bid functions. The highest bidder uses the land and the model this predicts separation of groups of workers. In this generalized monocentric model the slope of the bid rent functions is the driver of the location of different groups within the urban area. The simple rule is that the group with the steeper bid rent curve lives closer to the employment center.

This slope is the ratio of the transportation cost and housing consumption. To see the implications of the model, we turn to a more general setup than the one used above and take into account the time cost of commuting. In fact, transportation costs are dominated by time costs, and the value of time is usually thought to be proportional to the wage, which implies that it is approximately proportional to income. As the income elasticity of housing consumption is often found to be between 0 and 1, this suggests that the bid rent curves of households with higher incomes will be steeper. The implication that higher income groups live closest to employment centers was for a long time at odds with 20th century reality in the US cities, which was somewhat discomfiting for the theory. In the 19th century the United States and in many European cities also in the 20th century many inhabitants of central city residential areas had high incomes. More recently, the popularity of (central) urban living among high-income households has been increasing worldwide. Apart from the good accessibility of employment, appreciation of amenities like historical centers, the presence of theatres and a variety of restaurants appear to play a role.^b A recent study for Denmark confirms that the income elasticity of commuting distances is negative ([Gutiérrez-i-Puigarnau et al., 2016](#)).

Decentralized Employment and Excess Commuting

Efficient Commuting Patterns

The monocentric model explains important aspects of cities that are in fact far from monocentric. Somewhat paradoxically, it is unable to explain the commuting patterns in actual cities. The logic of the model discussed in the previous section implies that with multiple employment centers, the urban area splits up into a number of labor market areas. That is, for each center there is a catchment area that is spatially separated from those of the other centers.^c If there is dispersed employment outside the centers, the logic of the model implies that the jobs outside these centers are filled by workers commuting in the direction of the dominant employment center, while wages for the dispersed job are such that these workers are indifferent between their actual job and one

^b We will return to amenities below.

^c The situation is perfectly analogous to the Christaller model in which each central place has its own market area and market areas do not overlap.

located in the nearby employment center. The implied star-like commuting pattern can be shown to be efficient in that it minimizes to total commuting distance traveled.

Actual commuting patterns differ significantly from this prediction. It was found that at a small geographical scale random allocation of workers to jobs provided a better approximation to reality than the efficient commuting pattern. Although these findings were initially considered to be alarming with respect to the validity of the logic underlying the monocentric model, it has become apparent that modifications of the model allow for a reconciliation of theory and empirics.

Insights From Job Search Theory

The labor market described by the monocentric model is an extremely simplified one. It assumes perfect information and perfectly homogeneous labor. It has been pointed out that the realization of the efficient commuting pattern requires that every mutually beneficial swap of jobs should be realized. That is, if there exists a pair of workers in the city who can both realize a shorter commute by switching jobs, they should do so. If not, excess commuting remains present. However, even if we look at homogeneous groups of workers, it seems highly unlikely that all such swaps will be realized. The way these workers interact with colleagues and their specific experiences in the past causes heterogeneity that prohibits the realization of such swaps. Even if the workers find them attractive, their employers may disagree (and vice versa).

The economic model of job search that has been developed since the 1970s can be placed in a spatial setting to study the consequences of limited availability of vacancies for unemployed workers for the acceptance of commutes. The “reservation wage” property of the optimal search strategy then translates into a “reservation commute” property that implies that a wide range of commutes can be accepted, depending on the arrival rate of job offers (Rouwendal, 1998). Although the implied commuting patterns are inefficient in the sense that they do not minimize total commuting distances, they result—in such models—from an optimal trade-off between accepting an available job and waiting until a better one is offered. Hence the excess commuting is a consequence of more fundamental imperfections of labor markets.

The discussion above refers only to the labor market, while adjustments can also take place via the housing market. However, it is clear that similar problems are present there. Consider two families of which the two workers can realize shorter commutes if they “swap” their houses. In many cases one, and probably both, will be unwilling to realize this exchange even if the housing market would have no imperfections. In fact, it shows similar imperfections as the labor market possesses. We may conclude that seemingly excessive commuting is at least partly caused by idiosyncratic preferences for particular jobs or houses and plays a useful role in mitigating the imperfections of the housing and labor markets.

Is Excess Commuting Productive?

Excess commuting can, from an alternative point of view, be interpreted as an indicator of the density and specialization of workers and jobs in local labor markets. Workers that reside in a large metropolitan area with many employment opportunities have the possibility to accept many jobs from a given residential location, whereas those living in an isolated town have little choice. The relevance of housing and labor market imperfections thus suggests that the presence of close-to-random matching of workers to jobs as far as the residential and employment locations are concerned may in fact signal the existence of a well-functioning labor market in which workers can easily switch from one job to another while avoiding the substantial cost of residential mobility. A measure of labor market density that can also be regarded as an indicator of wasteful commuting has indeed been shown to have substantial explanatory power in wage regressions for the United States (Gautier and Teulings, 2003). Idiosyncratic differences in the quality of matches between workers and jobs can more easily be exploited in dense urban labor markets and may be incorrectly interpreted as excessive. In line with this, it has recently been shown that in larger urban areas assortative matching between highly productive workers and jobs is an important source of higher wages in German cities.

Gravity Equations and Discrete Choice

The Logit Model

Physical analogies have been popular among economic geographers and the gravity equation has been found especially relevant as a model for spatial interaction. Commuting is no exception and a typical formulation is:

$$C_{ij} = R_i E_j f(d_{ij})$$

Here C_{ij} denotes the number of workers commuting from i to j , R_i the number of residents in i , and E_j the number of jobs in j , while f is a decreasing function of the distance d_{ij} between these two locations. Popular specifications of f are the power and exponential functions. An economic interpretation of this model can be found by assuming that a worker’s utility over combinations of residential and work locations is an additive function:^d

$$u_{ij} = a_i + b_j + c(d_{ij}) + \varepsilon_{ij}$$

^d An alternative, but equivalent, derivation starts from a utility function that is multiplicative.

where a_i denotes the utility of living in i , b_j , that of working in j and $c(d_{ij})$ indicates the quality of the match, which is typically a function of the travel distance d_{ij} , while ε_{ij} denotes the idiosyncratic utility that a worker derives from the combination. If it is assumed that the ε_{ij} are independent and identical extreme value type I distributed, utility maximizing behavior leads to the logit model. That is, the probability that the combination of residential location i and employment location j will be chosen equals:

$$\pi_{ij} = \frac{e^{a_i + b_j + c(d_{ij})}}{\sum_k \sum_l e^{a_k + b_l + c(d_{kl})}}$$

where the index k runs over all residential locations and l over all work locations. With alternative specific constants incorporated in the utilities of the residential and work locations, maximum likelihood estimation of the model guarantees $\sum_j \pi_{ij} = \frac{R_i}{\sum_k R_k}$ and $\sum_i \pi_{ij} = \frac{E_j}{\sum_l E_l}$.

The logit model has been heavily criticized for its independence of irrelevant alternatives, which is closely related to the assumed distribution of the idiosyncratic utilities. However, it has received new popularity because of its relationship to the gravity equation. Nevertheless, it seems plausible that the ε_{ij} are correlated. For instance, if a worker has a strong idiosyncratic preference for living in a particular neighborhood, this will be reflected in all commutes that have this zone as the residence. However, these strong a priori arguments notwithstanding, the multinomial logit model is hard to beat because with a full set of origin- and destination-specific constants its generalizations like nested and mixed logit are not identified.

Amenities

The gravity equation and the related discrete choice models can provide good approximations to actual commuting patterns. They can also easily incorporate amenities at the residential and work locations. That is, the utilities of those locations need not be determined completely by the wage and the housing price, but can also be affected by the presence of shops and restaurants, nice architecture, etc. For instance the model can explain “reverse commuting:” workers living in the center because of the attractive urban amenities, while working in the suburbs, where more suitable jobs are available.

Although the model has a prominent place for commuting costs, it is also consistent with the view that separation between employment and residential locations is a potential benefit, because employment locations are not necessarily the best places to live. Easy commutes make it possible to combine attractive residential locations with the most suitable jobs, which can improve welfare. For instance, it has been argued that the decrease in commuting costs occurring in the United States between 1990 and 2010 implied an increase in welfare of around 3.3%, which is of the same order of magnitude as opening the closed economy of a medium-sized country to international trade (Monte et al., 2018).

Commuting and Local Labor Markets

Shocks

A sudden increase in local labor demand is difficult to handle with an isolated local labor market since the housing stock is difficult to adjust in the short run. However, if local labor markets are overlapping the additional workers may be attracted from neighboring locations and the shock may be much easier to absorb. It has indeed been shown that the substantial diversity in the reactions of local labor markets to a positive shock in demand is related to the possibility to increase the number of incoming commuters. The local shock thus causes a ripple effect as the shortage of labor in one location is shifted to contiguous labor markets. Commuting thus plays an important role in local labor market adjustments (Manning and Petrongolo, 2017).^e

Overlapping local labor markets have been shown to be consistent with strong resistance against long commutes and effects of place based policies that reach much further than the average commute. The reason is a ripple effect. A shortage of labor expands over space as workers from nearby locations are pulled toward the location with high demand.

The resistance against accepting long commutes is strong. Although—what at first sight was thought to be—excess commuting suggested that workers do not really care about commuting, empirical investigations almost invariably show the contrary: workers need substantial compensation for accepting longer home-to-work distances.

Wages and Commutes

In the frictionless models, such as a standard monocentric city model, the wage is equal to the marginal productivity at the workplace location but does not depend on the length of the commute of the worker. In such markets we would not expect firms to (partially) compensate the commuting costs of their employees.

In imperfect labor markets with job search frictions,^f workers, and employers bargain about the wage conditional on the commuting distance and the surplus of the match is shared between workers and employers. Wages will be higher for workers

^e Of course, long run adjustments may be more in line with Rosen-Roback models in which the housing market adjusts so as to accommodate the larger number of workers at shorter average commutes.

^f Labor market characterized by incomplete information about job offers.

with a longer commute because a long distance makes the job match less attractive to workers. Moreover, if firms enjoy some monopsony power in the labor market, which allows them to pay wages below marginal productivity, they will compensate workers for longer commutes. Hence the difference between wage and marginal productivity will be largest for workers living next to the firm. The main reason is that opportunity costs of staying with the firm for workers who live close to the firm are less than those with longer commutes.

There is recent quasi-experimental evidence that workers who face longer commutes because of firm relocations receive a wage increase. More specifically, a one percent increase in commuting distance induces a wage increase of about 0.02%. The implied hourly wage compensation for an additional hour of commuting is of the order of 15%–20% of the net hourly wage (Mulalic et al., 2014).

This and related findings give second thoughts about the appropriateness of the standard assumption that employers do not compensate workers for commuting costs. The empirical evidence just referred to suggests that employers may at least partly compensate their workers for increasing commuting costs due, for instance, to the introduction of road pricing or other policy measures.⁸

Conclusion

Commuting is still a burden for the many workers who experience traffic congestion on each working day. But it also implies the significant advantages associated with separating residential and work locations. Agglomeration benefits in production and consumption can be better exploited in this way. Moreover, dense labor markets offer workers access to larger numbers of jobs from a given residential location and firms to a large number of workers for their jobs, without having to relocate. On top of that, commuting can play an important role in labor market adjustments following local shocks. All this implies that commutes play an important role in the functioning of local and regional labor markets. These markets should be regarded as imperfect with respect to the availability of information about matching opportunities and competitiveness. The seemingly random commuting patterns observed at small geographical scales do not prove that commuting is wasteful, but result from the fact that commuting choices do much more than minimize the distance between home and work. Commuting costs are high and the social benefits of reducing them through improvements in transportation infrastructure remain large.

Introduction

Transport infrastructure could in principle be provided by private companies charging users when using the system. However, transport infrastructure is generally owned by the state. This is justified by the transport infrastructure having elements of natural monopoly, that is, there are economies of scale and scope in having the state providing this service. Monopoly pricing can be a significant burden on efficiency.

The setup with a public client entails a decision to build and maintain the infrastructure in-house using publicly employed staff or to contract out the work to private companies (Shleifer, 1998). This can be modeled as a public *make-or-buy* decision.^a There are pros and cons to both alternatives, but over time most western countries have come to contract out transport infrastructure construction and maintenance.

Given that the public client chooses to procure the work, the question is how to design such a contract. Most countries have some version of a public procurement law, stipulating that the public client should accept the lowest price or the most economically advantageous tender.

The *raison d'être* of public procurement laws are to secure efficient spending of tax money and deter nepotism. Although desirable features, the legislation reduces the public client's possibilities to procure products. Private clients are free to choose any contractor they want without having to justify it. This includes using a self-enforcing and infinite contract, meaning that a contractor doing a good job can also be awarded the next job without any external restriction on how the second contract was won. This creates an incentive for the contractor to do a good job (Gibbons, 2005). The self-enforcing contract cannot be copied in full by the public client, as each contract needs to be procured in a transparent matter. Without the option of signing self-enforcing contracts, the contract design for the public sector becomes more complex.

The challenge when tendering transport infrastructure is how to design contracts that minimize cost subject to a prespecified dimensions of quality. One could in principle maximize quality subject to a budget constraint, but that is not how it usually works in reality, as quality is hard to specify and monitor.

This paper concerns the buying and construction of transport infrastructure project, that is, a cost-efficiency perspective. Socioeconomic efficiency is an issue for the planning stage before the procurement. The pros and cons of the three most common contracting forms will be described.

Three Contracting Forms to Buy Transport Infrastructure

Over time, three types of contracts have been developed for buying transport infrastructure in the public sector. The taxonomy differs between countries, but a common way of describing the three contracting forms is design-bid-build (DBB), design-build (DB), and public-private partnerships (PPP).

^aThe make-or-buy decision refers to the theory of the firm, granted with two Nobel prizes—Coase (1991) and Williamson (2009), where the size of the firm is decided by using the market to buy inputs or make the product in-house.

In a DBB contract, the client is responsible for the design and the contractor for the construction. If a bridge collapses because of an under-dimensioned pillar in the design, the client is accountable. However, if it breaks down due to the contractor not building in accordance to the design, it is the contractor's responsibility.

The DB contract makes the contractor responsible for both design and construction. Instead of giving specific instructions on how to build, the client expresses the transport infrastructure project in terms of functional requirements (e.g., travel times between cities A and B) and then the contractor comes up with the design and undertakes the construction.

PPP can be described as a version of the DB contract, but where the contractor apart from construction also will be responsible for funding and maintenance. As the contract includes maintenance, the contract duration is typically longer. Payment is received after the completion of the investment, entailing that the contractor needs to fund the project.

The Traditional Way of Building Transport Infrastructure—DBB

The DBB is the traditional and still most common contracting form in the construction industry. It is procured with the client providing a bill of quantities. This is a list of the tasks required to build the infrastructure and their respective quantities, for example, square meters of asphalt, cubic meters of gravel, number of signs, etc. These quantities are connected to technical descriptions and manuals. Contractors then submit bids in the form of price vectors, one unit price for each quantity. The lowest vector product of prices and quantities, that is, the lowest total price, is awarded the contract and takes legal responsibility for the construction. The payment within a DBB can be fixed, cost-plus, or incentive scheme with a target cost.

The fixed price contract stipulates that the client pays the contractor a predetermined price regardless of the final project cost. The price p coincides with lowest tender b , as:

$$p_i = b_i, \text{ where } b_i = \min\{B_1, B_2, \dots, B_n\}, \quad (1)$$

where B_{1-n} are the independent bids. In this setup, the contractor has a strong incentive to cut costs in order to maximize profit. Under the assumption of ex-post information asymmetry, this can entail shirking on quality. However, the difference between the price and the actual cost may also be positive. Both deviations from the price are carried by the contractor who bears all risk under a fixed price contract.

On the other side of the spectrum, there is the cost-plus contract with the client bearing all the risk. The price, p , that the contractor is paid coincides with his cost, c , as:

$$p_1 = c_1, \text{ for Contractor 1} \quad (2)$$

Here, the incentive for the contractor to hold back costs is weak but there is no reason to shirk on quality.

The third contract is a hybrid of the earlier versions and is called an incentive or a profit-sharing contract. It establishes a target price b obtained from the lowest tender. Any deviations depending on the winning contractor's costs in c is split between the parties by a predetermined weighting parameter α , as:

$$p_i = b + \alpha(c_i - b) \quad (3)$$

The weighting parameter, α , is a matter of negotiation, depending on both the risk aversion of the parties and whether the client favors high quality or low cost in terms of contractor incentives. This contract requires open accounting and therefore more transaction costs.

As the contractor carries risk in the fixed price and incentive contracts, these are expected to have a higher price due to a risk premium.

How the contracting forms affect ex-post cost is, however, not that obvious. Two opposing mechanisms can be distinguished. In theory, cost-plus contract's lack of incentive to hold back cost during the contract could outweigh the risk premium of the fixed price contracts. Empirical studies comparing outcome of the payment schemes are lacking.

A Refined Model DBB Contracts

An important feature of applied research, such as transport economics, is that the results need a link to real-life situations and stakeholders' decisions. A problem with the standard descriptions of the DBB contract as described earlier [Eqs. (1–3)] is that there are no such clear-cut versions in reality. Everyday contracting is much more complex. The real design of the payment scheme in a DBB is the unit price contract (UPC).

A UPC consists of unit prices from the contractor and adjustable (q_i) and nonadjustable ($\bar{q}$) quantities, which are specified in ex ante in the tendering document by the client. This gives a new cost function, as follows:

$$p = b = c = \sum_{i=1}^n ap_i q_i + \sum_{j=1}^m ap_j \bar{q}_j \quad (4)$$

where $i = 1, \dots, n$ indicates adjustable quantities (q_i) and $j = 1, \dots, m$ indicates nonadjustable quantities ($\bar{q}$) and their unit price vectors ap_i and ap_j .

Applying this more detailed cost function [Eq. (4)] into the cost-plus contracts [Eq. (2)] gives:

$$p = \sum_{i=1}^n a p_i q_i + \sum_{j=1}^m a p_j \bar{q}_j \quad (5)$$

The second part of Eq. (5), regarding $(\bar{q})$, adds a fixed element to the cost-plus contract by pushing over risk to the contractor.

The introduction of adjustable quantities also changes the fixed price contracts [Eq. (1)] as the client will take some risk. Formally this can be described by b no longer being fixed ex post as:

$$p = b = c = \sum_{i=1}^n a p_i q_i + \sum_{j=1}^m a p_j \bar{q}_j \quad (6)$$

Hence, by introducing adjustable and nonadjustable quantities, the fixed-price and the cost-plus contracts turn into the same specification, as follows:

$$p = b = c = \sum_{i=1}^n a p_i q_i + \sum_{j=1}^m a p_j \bar{q}_j \quad (7)$$

Eq. (7) is a combination of [Eqs. (1) and (2)], with the adjustable quantities representing the cost-plus contract and the nonadjustable quantities representing the fixed price. A UPC with only fixed quantities or only adjustable quantities would collapse [Eq. (7)] to a fixed price [Eq. (1)] and cost-plus [Eq. (2)] contract, respectively.

Including adjustable and nonadjustable quantities to these models improves the connection to reality and enables a better understanding of how these contracts work in order to make better projections of outcome. The extended model opens up for analysis concerning problems discussed in the industry regarding, for example, the problem with cost overruns in transport infrastructure projects.

Cost Overruns in Infrastructure Project

In a world of costless and complete information with no uncertainty, designing a contract would be easy as every eventuality could be specified in detail. However, full information is not a fair assumption and complete contracts cannot be written. This is because (1) all contingencies cannot be foreseen, and, even if they could, it would be (2) infinitely expensive to write all of them down. Even if both (1) and (2) would be fulfilled, then (3) the language is not clear enough to describe everything in such a way that there would be no problems of interpretation and enforcement.

Hence, in a world of incomplete contracts, problems occur when new information arrives. One well-documented problem when building transport infrastructure is cost overruns. Infrastructure projects tend to swell both in size and cost after the political decision to build has been taken. This is due to the somewhat trivial but theoretical important explanation that complete contracts do not exist in reality.

There are three hypotheses to explain cost overruns (Flyvbjerg, 2009):

1. Psychological explanations—indicating an optimism bias from the people working with the project during the planning stage.
2. Political-economic explanations—indicating a deliberate push for underestimating negative and overstating positive aspects of the project.
3. Technical explanations—indicating that some technical aspects such as type of geology or rock type were misestimated.

There are two categories of cost overruns. The first refers to a deviation between the final cost and the estimated cost when the political decision to build was made. The second type compares the procured price and the final cost. Although most transport infrastructure projects exceed both planned and procured cost, there are examples of project going under budget and ex-ante price.

All of the hypotheses earlier concern the planning stage of a transport infrastructure project and the first type of cost overrun. Focusing on second type cost overrun, the contract design has to be analyzed which originates in technical explanations (3). Building on technical explanations, the causes for cost overruns can be further developed into the following three different aspects:

- 3a. Misestimations of stipulated quantities in the tendering document. This relates to deviations in Eq. (7) regarding q .
- 3b. Ex-post adaptation, where the cost will grow due to quantities that was not included in ex-ante tendering documents.
- 3c. Strategic pricing from the contractor making use of misestimations, either of type (3a) or (3b).

The former two explanations are due to client mistakes, but the latter concerns deliberate strategic behavior from the contractor based on superior information.

Cost overruns because of the client (3a–b) are solved by more planning and better designs. In order to mitigate cost overruns due to contractors setting strategic prices (3c), the contract design needs to be analyzed.

Strategically Set Prices

An example of strategically set prices in UPCs is unbalanced bidding (Ewerhart and Fieseler, 2003). This pricing strategy is done by raising unit prices on underestimated quantities and vice versa to compensate for a competitive bid. The contractor will attain rents due to asymmetric information and the skewing of unit prices, for example, by the following example.

Table 1 Ex-ante bill of quantities and bids

<i>Ex ante</i>	<i>Bill of quantities</i>	<i>Contractor 1's bid (uninformed)</i>	<i>Contractor 2's bid (informed)</i>
Provision of gravel	100 m ³	10	12
Pavement	150 m ³	10	8.5
Total bid		2500	2475

Table 2 Ex-post quantities and revenue

<i>Ex post</i>	<i>Actual of quantities</i>	<i>Contractor 1's bid (uninformed)</i>	<i>Contractor 2's bid (informed)</i>
Provision of gravel	110 m ³	10	12
Pavement	145 m ³	10	8.5
Final cost for the client		2550	2553

Table 3 Contractor 2 being risk-neutral

<i>Ex ante</i>	<i>Actual of quantities</i>	<i>Contractor 1's bid (uninformed)</i>	<i>Contractor 2's bid (informed)</i>
Provision of gravel	110 m ³	10	25
Pavement	145 m ³	10	0
Final cost for the client		2500	2750

Assume that there are two inputs to building a road, provision of gravel and pavement. The ex-ante bill of quantities for the project estimates 100 m³ of gravel and 150 m² of pavement. Assume further that the contractors differ in costs and information, where Contractor 2 has a higher marginal cost on both inputs in comparison to Contractor 1. However, Contractor 2 also has private information on the amount of gravel and pavement, which Contractor 1 does not. Contractor 1 bids her marginal cost at unit prices of 10. Contractor 2 can use the superior information regarding the ex-post quantities and skew unit prices accordingly. As depicted in **Table 1**, Contractor 2 submits the lower total bid and wins the contract.

The project starts and Contractor 2's prediction that the quantities of gravel will increase and pavement will decrease turns out to be correct. As seen in **Table 2**, Contractor 2's skewing of prices, based on her expectation of changing quantities, enables her to win the contract and earn higher revenue.

Due to unbalanced bidding, the most efficient contractor with the lowest marginal cost will, in this example, not win the contract and the client ends up paying an information rent to Contractor 2.

However, assuming that the contractor is risk neutral, the optimal way of skewing the bid is to hand in zero-unit prices expect on the most underestimated quantity, as seen in **Table 3**.

Such bidding behavior would maximize the ex-post profit. Both European and US data indicate that this problem exists but that the amount of skewing is low.

In the general discussion regarding unbalanced bidding, firms are often framed as morally reprehensible. Such a framing could be criticized, as it would not be possible without the deficiencies in the bill of quantities produced by the client. And if the Contractor 1 would not exploit these deficiencies, then Contractor 2 would. Hence, superior information and strategically set prices is a way to compete, that is, best mitigated by improved design of the contracts.

Another version of strategically set prices is when the contractor exploits the fact that the client has missed some quantities in the ex-ante tendering documents, referring to 3b earlier. The client can use this mistake to lower the total price of the bid, by, for example, lowering all unit prices with 10%, in order to win the contract and raise the price on expected extra work. This requires that the contractor has better information than the client regarding what is required to build the transport infrastructure.

The Push for DB Contracting to Enhance Productivity

There is a general view that the productivity in the construction industry is lagging compared to other industries. Empirical macro-studies, mostly on labor productivity but also using data on capital and total factor productivity, support this view. Arguments that it is hard to deflate quality improvements in construction compared to other industries have been put forward as a way to nuance the low productive.

In the quest for higher productivity, there is a trend both in the United States and in Europe to push for using DB contracts at the expense of the traditional and still most commonly used DBB contracting. DB contracting gives the contractor more degrees of freedom in the design, which enables them to come up with new solutions and innovations. Such incentives are missing in a DBB contract, where the client provides the design and the contractor builds accordingly.

The theoretical underpinning for DB contracting providing incentives to innovate is rather straightforward, but there is a lack of statistical empirical studies supporting this claim. A hypothesis for the lack of empirical studies is the difficulty of getting a representative dataset regarding final cost on project level. There seems to be a generic problem within transport infrastructure construction with a lack interest for ex-post evaluations of costs and projects.

In the absence of empirical facts, public clients in Europe and the United States, equipped with theoretical arguments, have pushed for DB contracts. This push has been undertaken by setting up quantitative targets for the introduction of DB contracts. Examples include that 50% of all contracts were to be DB before 2018. These quantitative targets were fulfilled by relabeling DBB contracts as DB without any substantial change. The push for DB contract with the purpose to promote innovation is still present in many countries, but the change is slow.

PPP is Not a Way to Raise Funding

The usage of PPP to provide transport infrastructure is far from a new concept. An old Swedish example dates back to 1886, where a contractor was given a concession to build a tunnel for walking in central Stockholm and the right to take out a toll.

The definition of a PPP is the bundling of construction and maintenance into one long contract (at least 15 years), with the contractor putting the funding. Payment is received by tolls, shadow tolls paid by the public client or a combination of the two (Hart, 2003).

There are two theoretical arguments for PPPs. The first one is the incentive for the contractor to optimize the life cycle cost (LCC) perspective through bundling, as it is also responsible for the maintenance. In comparison to DBB and DB contracts, the PPP provides the contractor with the opportunity to build at a high initial cost to save money on maintenance. The second argument coincides with a DB contract, as a PPP gives the contractor degrees of freedom to find innovative solutions.

An argument against PPP is that the public client often has a lower capital cost than the private contractor. This is true for countries with sound public finances, but the lower capital cost must be weighed against the potential efficiency gains in terms of innovative solutions and optimal LCC that would not have been incurred otherwise. For countries with weak governmental finances, PPP becomes more interesting.

A pragmatic but insidious argument for PPP with shadow tolls is that it pushes the cost for new infrastructure onto future state budgets. This is handy in a shortsighted political perspective with new infrastructure paid by future taxpayers and still financial room for reforms today. Such reasoning is not a valid argument, as the transport infrastructure must be paid sooner or later, which encumbrance future state budgets. However, it is a real argument from a political perspective as the decision-makers might not be around when the bill is due.

Another argument against PPP, based on anecdotal evidence from southern Europe after the financial crisis in 2008 and more recently with regional Chinese public clients, is the lack of negotiating skills of the public side. Big construction companies with venture capital negotiate these contracts with commercial lawyers that the public client often cannot match. There are quite a few examples, where the public clients have signed contracts paying too much ex post.

Pros and Cons of Contracting Forms to Buy Transport Infrastructure

Like all problems in economics, there are pros and cons with all three contracting forms that are used to buy transport infrastructure. Statistical empirical analysis of contracting in the construction sector does not provide a lot of guidance. The studies that do exist are primarily based on road construction data in the United States. These studies focus on different subsections of the contracting decision, such as strategically set prices in DBB, the possibility to renegotiate contracts, the effect of having worked together earlier, etc., but not the overhauling question on which contracting form to use depending on different circumstances.

For this question, theoretical conclusions are still of guidance. To summarize there are theoretical pros and cons to each contracting form according to Table 4.

Table 4 Pros and cons on contracts in transport infrastructure construction

	<i>Pros</i>	<i>Cons</i>	<i>Comment</i>
DBB	Transparent and competitive procurement	Minor incentives for innovations	The most commonly used contracting form
DB	Incentives for innovations	Higher risk for contractor, therefore more expensive and less competitive	Problems with the so-called DB contracts that do not include degrees of freedom for the contractors
PPP	LCC perspective	More complex contracting negotiations	Political risk of being used as an “easy” way to finance infrastructure and sending the bill to future taxpayers

Summary

Most countries buy construction and maintenance of transport infrastructure from the market instead of undertaking in-house. Three ways of contracting can be distinguished. DBB is the traditional and still most commonly used way of tendering, DB gives the contractor incentives to innovate, while PPP improves the possibility to optimize LCC perspective. Empirical studies on which contract to prefer depending on external conditions are lacking. The future of this field is to model the contracts in more detail as the real contracts used do not coincide with the textbook definitions and gather data on final cost and quality to evaluate the efficiency of the contracts under different circumstances.

Introduction

The last 30 years have seen a global trend toward the involvement of the private sector in providing and funding a wide range of public services. The introduction of competition has formed a key part of the associated reforms alongside privatization of different degrees and types. Reforms to introduce private sector involvement and competition in the provision of public transport can therefore be seen as part of a much wider set of reforms, covering the utilities, and also public services in, for example, health, education, and a wide range of local government funded services.

There is a strong case for the involvement of government in the provision of public transport or at the very least in specifying the level of service required. It is therefore frequently considered that competition for the market (or ex ante competition) is a more appropriate means of introducing competition in public transport than competition in the market (or “on-road/on-track” competition). Under the competition for the market model, the government can specify what it wants to provide and then invite the market to bid for the exclusive right to provide these services on a given route or routes. This form of competition avoids the possible loss of economies of scale and/or density implied by competition in the market, while at the same time capturing the benefits of competition through the bidding process; also avoiding the costs of government ownership/provision or regulation. Where physical infrastructure is key to delivering public services, for example in rail, this form of competition may require some form of vertical separation (infrastructure from operations). Indeed, the notion of allowing competition between operators on a common infrastructure represents a significant rethink of regulatory policy in respect of network industries; where regulation of vertically integrated monopolies was previously considered the only option.

As discussed below, in most cases around the world public transport (rail and bus) is provided either by state-run bodies with no competition, or via competition for the market. In some cases, where there is no competition, this has occurred by a deliberate choice to allow an incumbent, who previously won the market based on a competition, to retain the market based on a negotiated settlement for some specified period. In other cases it is because public services have not yet been opened up to competition. There are also some examples of on-road competition in the bus market, provided on commercial terms, most notably in terms of developed markets in Great Britain (outside London); as well as in some developing countries and for long distance bus (and in a few cases rail) services more generally.

The article is structured as follows. The second section provides a brief introduction to the theoretical literature on anticipated benefits and issues associated with introducing competition for the market. In the third section the issue of how best to design competitive tendering exercises and contracts is considered. The fourth and fifth sections consider in turn experience of procurement in rail and bus sectors and the last section reaches conclusions.

Theoretical Perspectives

The benefits of competition in driving efficient outcomes have been long established. In the regulatory sphere, however, the notion of using competition for the market, in place of competition in the market, is relatively new (Demsetz, 1968). The general argument

Figure 1 Illustration of competitive bidding.

for this form of competition is that in the presence of natural monopoly, especially concerning infrastructure and also extending to service provision, means that competition may be hard to achieve. In public transport, there are further particular considerations. It can also be difficult for a sensible timetable to emerge from a competitive equilibrium, with the tendency for service bunching (Hotelling, 1929). Profit maximizing operators may have incentives to schedule services close to those of its competitors to gain passengers and as a longer-term strategy to drive competitors out of the market completely. This occurred in the British bus reforms in the 1980s, but such competition was rarely sustained, usually one or other operator left the market. There was also much use of anticompetitive practices such as running free buses in front of their services to drive out rivals, but this was tackled by tightening competition laws.

Moreover, the search costs involved in selecting one public transport operator over another on the same route mean that price competition may not emerge in some transport markets, at least on local services, where the convenience of getting on the first bus or train outweighs any saving in cost. Governments of course also perceive a central role in ensuring appropriate service levels in situations where services would not be profitable for a private firm, and in ensuring good quality, appropriately priced, and accessible public transport services. Improved public transport is also seen as a way of tackling the problems of congestion and pollution caused by excessive car traffic, particularly in large cities (Goeurden et al., 2006).

The alternatives, namely economic regulation of a private monopolist or state ownership, are also widely perceived to possess disadvantages. Competition for the market, in which firms compete for the monopoly right to supply a particular market, enables a competitive process to deliver good outcomes for consumers, while ensuring that only a single provider operates at any given time. Thus the optimal cost structure is retained, while avoiding problems of monopolistic practices. Further, there is no need for economic regulation, provided that the price of the service is the basis for selection in the competitive process.

In theory the competitive process therefore ensures that firms will bid no more than their average cost, thus preventing monopoly profits, while also ensuring that the most efficient firm wins (Fig. 1). Dynamic efficiency is also encouraged since once the contract is signed, firms have strong incentives to reduce costs and grow the market. It should be noted that in most public transport tendering processes, the degree of subsidy required (or in some profitable markets, premium paid) is the basis for selection. In this scenario it is necessary to specify the price regulation framework that will be implemented (otherwise firms, having won, could exploit consumers). More widely a contract is needed between government and the firm to specify, inter alia, the service required and its quality.

Overall competition for the market appears to offer the best of all worlds. However, its success depends on a number of critical factors. First there needs to be sufficient number of bidders, and the avoidance of collusion. Information asymmetries may also interrupt an efficient outcome—in particular, incumbent advantage could deter other companies from bidding. There is also the problem of winner's curse which may either mean that the winning bidder overpays and cannot fulfill the contract—putting the problem back to government—or that bidders bid too conservatively because of fear of winner's curse. Information is crucially important here to mitigate against such problems. To the extent that firms believe they can bid aggressively and then renegotiate—or in the case of naive bidding—the winning bidder may not be the best firm to run the services.

The ability to specify and enforce a contract that sets out what the government wants in terms of service level and quality can also be a problem, particularly where quality is hard to define, or where there is uncertainty about what the government will want in the future. Contract design issues are discussed in the third section. Finally, there may be issues regarding asset handover when services change to new operators following a competitive tender. All of these factors greatly complicate the theoretical predictions, and could undermine the potential benefits of this form of competition.

Issues in Contract Design

If the decision is taken to use competitive tendering as a way of procuring public transport services, a number of crucial questions must be considered. This section considers them, and the options that will be faced (Nash et al., 2019).

Franchising Authority

A country intending to use competitive tendering for procurement of public transport must establish a tendering authority with the skills and resources to draw up appropriate contracts, monitor performance and take enforcement action should the franchisee fail to deliver. That authority is usually an agency of central, regional, or local government, although sometimes it may be a joint authority covering several local authorities.

In many cases (e.g., regions in Sweden, states in Germany) the same authority is responsible for both bus and rail services and may also have wider responsibilities regarding planning and road infrastructure. This enables them to integrate decisions across the modes and with wider considerations. The authority also needs to be large enough to exploit economies of scale in the size of tenders (if economies of scale are exhausted at a smaller scale than the authority, then it may let more than one tender, as do many of the German federal states). But such a policy may remove provision of local bus services from the layer of government best able to determine needs, as local bus services are very much a local concern.

Net or Gross Cost Contracts

A key decision in letting contracts is whether to go for net cost contracts, in which the operator bids for a certain level of subsidy and takes all the risks regarding both revenue and costs, or a gross cost contract in which the operator bids for a payment to reimburse the costs of operating the service and pays the revenue to the authority, so bearing cost risk only.

There is often a strong presumption among economists in favor of net cost contracts, as these give the operator a strong incentive to boost revenue. However, net cost contracts may have disadvantages. They expose the operator to many risks outside their control, such as relating to the state of the economy and local employment levels, which are strong determinants of demand (while there are cost risks outside the control of the operator, such general wage trends and fuel prices, these are generally less critical than demand). But contracts may partially or fully protect the operator against externally determined cost risks as well). Sometimes such demand side risks are shared, for instance by paying the contractor a share of the revenue or by taking specific risks such as those associated with levels of employment or GDP.

Exposure to a high level of risk may discourage some operators, especially smaller ones who cannot pool the risks from a multiplicity of contracts, from bidding at all, and encourage those who do bid to build in a large risk margin to their bids. It may also lead to a high level of franchise failure, where operators become bankrupt or exercise rights they have under the contract to withdraw early, giving the authority the cost and challenge of keeping services running (sometimes at short notice) and holding a premature competition for a new contract.

The choice of net versus gross contracts is often linked to the issue of how far operators are left to plan services and set fares. If operators are left a lot of freedom under the contract, subject to providing a minimum service level, then it is particularly important to give strong incentives to increase patronage and revenue, so a net cost contract may be most appropriate. If on the other hand a franchising authority itself wishes to determine timetables and fares, then the ability of the operator to influence revenue is very limited, and a gross cost contract with some quality incentives (see further) may be most appropriate.

Size and Scope

The issue here is geographical size of the contract and whether it covers a single mode or all public transport modes in the area. Linked to this is the question of whether both regional- and long-distance traffic should be included in franchises or whether they should be franchised separately (or indeed whether long distance transport should be left to commercial operators without a franchise). Practice ranges from contracts to cover all modes for metropolitan areas, down to individual bus routes. The size needs to be large enough to exploit any economies of scale (but not beyond the level at which diseconomies set in; see the fourth section). As noted earlier the size needs to be compatible with the area covered by the tendering authority and—particularly where planning is left to the train operator—compatible with the sensible planning of services. Thus, for instance, rail services into cities often fulfill a regional role and could not sensibly be divided into franchises covering individual cities.

There are advantages to covering all modes in a single tender, especially if the operator is responsible for planning services, but this has the disadvantage that evidence appears to suggest that the minimum efficient size for rail tenders is much bigger than bus, and the resulting large tender size may prevent smaller bus operators from competing. The problem does not arise if the tendering authority completely plans services and fares as it may then let separate contracts of differing size for bus and rail.

Length

There are also difficult trade-offs to make regarding contract length, which again interact with other aspects of the contract. Sometimes very short contracts, even as short as a year, are used. These maximize flexibility for the contracting authority in terms of future service changes and maximize competition by granting a monopoly for a very short period. But they may not be attractive to operators, because of bidding and start-up costs which must be recovered in a very short time, and thus may only attract a small number of bids which may not be very competitive. They clearly give no incentive for investment, whether in physical assets (which may be minimized depending how the ownership of assets is organized—discussed below) or in marketing, planning or improving the efficiency of working practices. They also involve all the costs of competition, for authority and bidders, at very frequent intervals.

On the other hand, it is possible to go for a long franchise—franchises exist of up to 25 years. But long franchises also have their problems. They grant a monopoly for a long period of time, while break points may be built in under which continuation of the contract is dependent on performance, if these are too rigorous they may lead the operator to regard the contract as a series of shorter ones from the point of view of risk and investment. They inevitably require a process to be determined for changes in services in the light of developments, as these cannot sensibly be specified for the full contract period, and for how this impacts on payments under the contract. This may be a time-consuming and contentious issue, as both parties may try to take advantage of the situation to achieve outcomes favorable for themselves. In such circumstances the question as to whether a standard regulatory model might be preferred to competitive tendering is pertinent.

Assets

As noted earlier, ownership of assets—rolling stock, depots, terminals—is a key issue in considering contract length. If the operator is required to supply all of these, then clearly a long contract, or some other way of relieving the operator of the residual value risk (such as guaranteeing the taking over of the assets by the succeeding operator at a fair price) is needed. Moreover, ownership of the assets will give the incumbent a strong advantage in any bidding process.

Thus for expensive assets, such as terminals, depots and rail rolling stock, there is a trend toward ownership by the franchising authority. That may also have disadvantages, in that the operator may be deemed to have a stronger interest in and ability for the efficient choice of assets. Sometimes assets, especially rolling stock, may be leased by third parties, but that does not fully resolve the problem, as they may still perceive a residual risk in short leasing agreements, particularly in the case of specialized equipment.

The much lower cost and more active second hand market in buses means these issues are much less significant in bus contracts than rail. Thus even where the operator is required to provide the buses, bus contracts of 5 years or less are common.

Incentives

With a net cost contract, operators should have strong incentives on both cost and demand sides, although the demand side incentives will be weaker on heavily subsidized services (where revenue is small relative to costs) than on more commercial ones. As noted earlier, the need for demand side incentives is much stronger with gross cost contracts than net, although they may be applied to both.

Usually contracts will include a set of key performance indicators covering issues such as crowding and reliability, which may be linked directly to financial incentives, or which may simply be contractual requirements, failure to achieve which would put the operator in breach of contract. This may lead to the requirement for remedial action, with the possibility of termination of the contract if the action is deemed inadequate.

The extent to which quality is a factor in the award of the contract also varies. Usually, there will be a prequalification procedure, which rules out any bidders who are not deemed capable of providing the services at the required quality, or who have inadequate finance. Particularly where the operator is responsible for planning timetables and procuring assets, their proposals regarding these factors may be given a weighting in the decision as to who should win the contract, alongside the financial attractiveness of the bid.

It may also be thought that in some cases additional incentives are necessary to reduce costs, particularly where the costs of challenging the cost base are disproportionate to the length of contract. In Great Britain, relatively short franchises, combined with a strong union, performance related penalties and loss of farebox revenue from a prolonged industrial dispute, have meant that operators have not sought to challenge the cost base as might be hoped. This is particularly so because at franchise replacement a new bidder takes over an existing company with the same staff and rolling stock. It may therefore be thought necessary to mandate the implementation of particular initiatives, such as driver only operation, in the franchise agreement, backed up by the introduction of rolling stock with the necessary technology. To date, however, trade unions in Great Britain have been able to resist this cost saving initiative.

Treatment of Staff

An important issue in franchising is the treatment of the staff of the existing operator. The ability of an incoming operator to recruit its own staff, setting its own salaries and working conditions, may be important in achieving the cost reductions often ascribed to competitive tendering. But this creates great uncertainty for the existing staff, and may worsen staff salaries and working conditions. Moreover it may lead to difficulties in terms of the new operators being able to recruit the staff they need, particularly if tendering is occurring on a large scale. Thus in many cases the new operator is required to take on the existing staff at existing salaries and working conditions.

Vertical Separation

Competitive tendering is often associated with vertical separation of infrastructure from operations, for rail as well as road based public transport. But arrangements are then needed to ensure that infrastructure and operations are planned to optimize the system as a whole. This issue is considered in another article and is therefore not pursued here.

Experience in Rail Transport

Europe offers the richest evidence on the impact of competition for the market for passenger rail services (Nash et al. 2019), though there have been examples elsewhere, for example in Australia and South America. Within Europe, competitive tendering has advanced furthest in Britain, Germany, and Sweden, though other countries such as the Netherlands, Norway, and Poland have also introduced some competitive tendering. The latest reform impulse from the European Commission, the 4th Railway Package, requires all public service contracts to be subject to competitive tendering by 2023, unless good reason for a direct award can be established. For commercial services, open access must be introduced by 2020 unless this threatens the financial equilibrium of a public service contract (this has been the arrangement for international services since 2010). Long distance services in Europe to date have typically been operated by the incumbent rail operator, but with new entry being permitted on an open-access basis in some cases. Such entry has occurred on main routes in Sweden, Italy, Austria, and the Czech Republic and to a very limited extent, in Germany and Great Britain. In respect of domestic long distance services, Great Britain is the exception, having chosen to franchise almost all long distance services, with a very small level of open-access competition alongside the franchise model.

For regional rail services, competitive tendering has been the chosen model where liberalization has occurred. Great Britain franchised all such services and importantly did not allow the former state-owned operator, British Rail to bid (British Rail effectively ceased to exist). This approach differs from that taken in Germany and Sweden where the incumbent operators were permitted to bid. In Sweden almost all such services have been subject to competitive tendering. In Germany only part of the regional services market has been opened up to competition. As of 2015, the incumbent (DB) still operated 70% of regional passenger train-km (Nash et al., 2019).

In respect of patronage growth, the European reforms can be seen to be very successful, though there is always the problem of establishing the counterfactual (Nash et al., 2013). Very strong growth in passenger-km was achieved in the three most liberalized markets (Great Britain, and regional services in Germany and Sweden). Great Britain, for example, saw usage more than double between 1995 and 2013. However, econometric models suggest that only part of this growth can be attributed to franchising (Preston and Robbins, 2013; Wardman, 2006). Rationalization—transfer of responsibility for specifying services to regional government—may also be associated with some of the growth in Sweden and Germany, while also growing the market in France even with a state-owned, monopoly provider. While net cost contracts are widely considered to have been successful at growing the market in Great Britain (though noting the franchise failure issues discussed below), Sweden, and Germany have both achieved strong patronage increases despite greater reliance on gross cost contracts. There is no clear evidence as to whether longer franchises work best in this respect, as a mix of franchise lengths have been used across all countries.

Turning to cost, tendering has been successful in Germany and Sweden, with reported savings of the order of 20%–30% per train-km. However, one issue is that these savings relate to subsidies rather than costs, and where net cost contracts are used the reductions could reflect revenue growth rather than cost savings (though Germany and especially Sweden have tended to use gross cost contracts to a much greater extent than Great Britain so subsidy reductions are likely to be more reflective of cost falls). In Great Britain unit costs have instead risen by between 16% and 25% (per vehicle-km and train-km, respectively) over the period since franchising (Smith, 2016). Costs per passenger-km have fallen however because of the sharp rise in demand (average loading has risen). Overall subsidies per train-km (infrastructure and operations) were lower in 2015 than at the time of the reforms, though having almost doubled in the intervening period. It may therefore be said that tendering in Sweden and Germany has been relatively successful, whereas cost control in Great Britain has been a significant problem.

The reasons for the different cost experiences are complex. One possible explanation is that the greater use of gross cost contracts in Sweden and Germany has encouraged focus on cost control, whereas in Great Britain there has been a strong emphasis on revenue growth. Also in Great Britain, when a franchise changes hands the incoming winner of the competition takes over an existing company, thus taking on the existing staff at existing wages and conditions. It has been argued that this approach, combined with relatively short franchises, and the penalties and lost revenue associated with industrial disputes, has created little incentive to operators to challenge the cost base. Elsewhere in Europe, the entrant has been free to recruit new staff at new wages and conditions, the existing staff having the option to remain with the previous operator (although this is no longer the case in Germany).

The most recent evidence suggests that some of Britain's rail franchises are too big from a cost perspective (likewise some of the larger German franchises). While longer franchises have been suggested to encourage longer term thinking in terms of cost reduction there is little evidence to suggest that this has been effective in Great Britain and a range of franchise lengths has been used across the different countries. There is some evidence that longer franchises have encouraged better rolling stock deals in Germany. In Great Britain problems of cost control and operational issues have been linked to vertical separation and numerous efforts have been made to enable greater coordination.

A significant problem in Great Britain has been franchise failure (this has been much less of a problem in other European countries, but it also occurred in Melbourne and South America). In the early period after franchising a number of companies failed after making too optimistic projections particularly about the degree to which they could reduce costs. More recent problems have emerged repeatedly on one of Britain's most profitable inter-city routes, the East Coast Main Line with three different companies failing in succession and withdrawing early. Thus it appears that winner's curse has been a problem to contend with.

For profitable routes that can be provided by the market, net cost (rather than gross-cost) contracts are clearly the most appropriate, assuming tendering is used as opposed to open-access competition. However, there are risks that lie outside the control of the operators, given the importance of the state of the economy in particular on trends in passenger journeys. For large franchises, these risks can be substantial. Various risk sharing approaches have been tried (linking franchise payments to revenue or GDP) and

also increasing financial penalties/capital requirements in the event of franchise failure. None of these approaches has yet been successful (if success is judged by seeing a franchisee fulfill their contract). In other European countries commercial services are provided by the incumbent railway, with open-access competition. Increased use of open-access is under consideration in Great Britain as well.

Experience in the Bus Sector

As noted earlier, local public transport is very often in the hands of a public sector monopoly operator owned by the local authority; less often there is a private sector regulated monopoly. Some countries, mostly in developing countries, leave public transport up to unregulated private companies competing on the road; in developed countries this approach is more often used for inter urban and long distance services. Finally, competitive tendering is in fairly common use ([Hensher and Wallis, 2005](#)), for instance for all services in Sweden and many in Germany, Norway, Denmark, and the Netherlands as well as some cities in the United States, Australia, and New Zealand. Most often competitive tendering takes place at a route or corridor level but sometimes (for instance in France and Spain) the entire public transport system of a city is let as a single contract.

Britain is unique in having simultaneously in 1986 introduced competition for the market in London, and for unprofitable services elsewhere, and competition in the market for profitable services outside London. In its monitoring exercise, the government collected data on costs in both sectors. In the ten years following deregulation, cost per bus km fell in real terms by 45% both in London and elsewhere, reversing a long-term upward trend ([Nash, 1993](#)). It should be noted that this reduction is somewhat exaggerated by the fact that some costs (e.g., of timetabling, publicity and provision of bus stops/shelters) remained with local authorities, and also there was a trend to smaller buses, but that there was a very substantial reduction, only partly at the expense of the wages and conditions of staff, is clear ([Heseltine and Silcock, 1990](#)). Both fares and service levels rose under both regimes, although in London it was a deliberate decision by the local transport authority, whereas elsewhere it was a market reaction (outside London services are provided on commercial terms in most cases). With few exceptions it appears that price competition was relatively ineffective in the local bus industry; passengers tended to take the first bus to come regardless of price, so service frequency was more important to competitors than price. But it should be noted that on the street competition has been comparatively rare; most of Britain has bus services provided by unregulated private monopolies ([Competition Commission, 2011](#)), but subject to the threat of entry.

However, there has been one big difference in the experience of on and off the street competition. In London, there was a modest rise in bus patronage over this period (more recently, the growth has been much stronger but in the context of increased subsidies to improve the fares and service level mix). But elsewhere in Britain bus patronage continued its downward trend. It is of course the case that as by far the largest city in Britain London offers a more favorable environment for bus operation, with denser population and lower car ownership than elsewhere. But [Fairhurst and Edwards \(1996\)](#) find that partly this more favorable trend in London was due to better integrated services; failure elsewhere to plan around regular interval services and common fare structures meant that patronage was below what might otherwise have been achieved with the service frequency and fares observed. In the light of this experience, there has been a move to secure better quality and better planned services through the use of quality partnerships between bus companies and local authorities, in which both parties agree to cooperate to raise the quality of bus services, and recent legislation makes the adoption of quality contracts (essentially the London model) elsewhere in Great Britain easier to implement ([White, 2018](#)).

In general, the experience of competitive tendering elsewhere is that it has also achieved significant cost savings ([Hensher and Wallis, 2005](#)), although generally lower than in Britain, and quite variable with circumstances (such as whether the incumbent was publicly or privately owned). What has been observed, however, is that usually competitive tendering after the initial round does not produce more cost savings, and indeed often some of those from the first round are lost. There seem to be a variety of reasons for this. In part it reflects tighter quality standards over time (e.g., new or better vehicles). But Hensher and Wallis argue that it also reflects a learning process on the part of bidders (such as a decline in the number of unrealistically low bids) and possibly also a decline in the amount of competition over time. They argue that, therefore, once an efficient operator has been assigned to a route, negotiated contracts, based on benchmarking to ensure the continued efficiency of the operator, and with performance incentives built into the contract, might have advantages over further competitive tendering. For instance, they avoid the costs of competitive tendering (although obviously having costs of their own) and the disruption of a possible change of operator, and might be more effective in encouraging innovation and the increase in traffic levels.

Conclusions

There are many choices to be made when implementing a system of competitive tendering and the choice between them involves difficult trade-offs. Decisions are also interdependent, as some packages make more sense than others. For instance, there may be a choice between long net cost franchises with ownership of assets and considerable freedom over planning of services and fares by operators (most suitable for commercial services), and short gross cost franchises with the franchising authority providing the assets and tightly specifying timetables and fares. The best approach is likely to vary greatly with circumstances such as the geography of the services, the modes involved and the level of subsidy. What follows is that franchising is a skilled business on the buyer side,

requiring staff with appropriate ability and experience. Where it is undertaken by many different local or regional bodies, sharing data and experience will be important to ensuring that it is undertaken efficiently.

Both bus and rail tendering are widespread in Europe and also to be found elsewhere. Overall it would appear that rail tendering has been successful in increasing patronage on public transport rail services in Europe, though other factors have also contributed to the growth, including rationalization. It also seems to have been successful in general in bringing about cost reductions across a number of countries, though Great Britain is an important counter case, having seen substantial increases in cost per train-km. Subsidies per train-km and passenger-km for tendered services have fallen across Europe, this being the case even in Great Britain, in the latter case driven by strong revenue growth. There is evidence that some of Britain's franchises are too big from a cost perspective (along with some of the larger German franchises), but while longer franchises have been discussed as a way of encouraging cost reductions, there is little evidence of their effectiveness in that regard, and longer franchises increase risk and reduce flexibility for funders.

A key lesson seems to be that gross cost contracts, perhaps combined with patronage incentives, work well for regional and suburban services where there is a regional government body with responsibility for setting fares and marketing services (perhaps supported by a public body to own and manage the rolling stock). Where gross cost contracts have been applied good performance on the cost and demand side has been achieved with few problems of franchise failure. Net cost contracts have been associated with high incidence of franchise failure, particularly in Great Britain. Part of the problem may lie in the choice that Great Britain made to use franchising even for commercially viable long distance services (in contrast to the rest of Europe) and where the size of the franchises increases risk and financial exposure to operators. Where competition has been introduced for commercial services elsewhere, it has usually been competition in the market, and this approach is under consideration in Great Britain.

The evidence from bus tendering likewise supports the theoretical prediction that competitive tendering will bring about cost reductions, although the savings achieved are quite variable and tend to be lower when the incumbent is already a private company. In the one case where local bus services are produced by competition in the market, Great Britain outside London, it appears that competition for the market has worked better in terms of patronage, because of better coordination of services, although the obvious differences between London and the rest of Great Britain make that conclusion tentative.

However, the evidence is that successive waves of tendering do not achieve further savings compared with the first one, and indeed that some of the initial gains are lost. That has led to the suggestion that negotiated contracts, with benchmarking to check costs and strong contractual incentives, may be a good option after the initial round of tendering. The evidence on this point is less clear in rail, although there has been a decline in the number of bidders over time and also a flight of private capital, with most bidders now being state-owned incumbents from the large European rail markets. But consideration of the application of negotiated, direct awards, supported by benchmarking, could be a useful dynamic in the rail sector also, especially in Great Britain where cost rises have been an issue.

Introduction

In urban economics, the mono-centric city model is a basic concept in modeling the spatial distribution of population in a city. It has been widely recognized as a useful tool in addressing the relationship between commuting cost, housing price, and housing consumption. It was developed in the 1960s and 1970s, largely through the work of William Alonso, Richard Muth, and Edwin Mills (Alonso, 1964; Muth, 1969; Mills, 1972). Although the modern cities have become increasingly polycentric, the mono-centric city model is still an important cornerstone for development of various city models (e.g., polycentric city models). In this chapter, we begin with the classic mono-centric city model, then describe some extensions of the classic mono-centric city model, and finally discuss some applications of the model in policy evaluation.

The Classic Mono-Centric City Model

In the classic mono-centric city model, the city is assumed to be on a featureless plain and transportation in the city is possible in all directions; all employment and goods and services are concentrated in a highly compact central business district (CBD); each location is only characterized by its distance from the CBD, and the travel time from any location to the workplace located in the CBD is a linear function of the distance between that location and the workplace, that is, the transport system in the city is radial and dense in all directions, and congestion-free; all households are homogeneous, implying that their income levels and utility functions are identical.

The household income is spent on transportation, housing and non-housing goods. Each household aims to maximize its own utility by determining the residential location, the consumption of housing and the amount of non-housing goods within a capital budget constraint. The household utility maximization problem can be represented as

$$\max_{z,g} u(z,g), \quad (1)$$

$$\text{subject to } Y - tx = z(x) + p(x)g(x), \quad (2)$$

where $u(z,g)$ is the household utility function, $g(x)$ is the housing consumption per household at location x , and $z(x)$ is the composite non-housing goods consumption per household at location x , for which the price is normalized to 1. Y is the average annual household income, tx is the average annual round-trip cost for households living at location x , and $p(x)$ is the average annual housing price at location x .

When the household residential location choice equilibrium state is reached, all households in the city enjoy the same utility level regardless of their residential locations. Denote u as such indifferent utility level. Then, solving the maximization problem (1)-(2) and setting the equilibrium utility $u(z,g) = u$, one can obtain the equilibrium housing rental price p , equilibrium housing consumption g , and non-housing goods consumption z , as functions of location x and the common utility u , represented as

$$p = p(x,u), \quad (3)$$

$$g = g(x, u), \quad (4)$$

$$z = z(x, u). \quad (5)$$

This basic model is useful in explaining the mechanism of trade-off between housing rental price and its proximity to the CBD. The housing rental price must decrease with x so as to offset the reduction in net income ($Y - tx$) due to an increase in the commuting cost.

We now look at the supply side of the housing market. The property developers determine the land and capital investment so as to maximize their net profit. Denote $H(x)$ as the housing production at location x . It is given by a constant returns-to-scale production function $H(x) = H(M(x), L(x))$, where $M(x)$ and $L(x)$ denote the inputs of capital and land at location x , respectively. Let $r(x)$ be the rental price of land at location x , and k be the price of capital (i.e., the interest rate). The net profit, $\pi(x)$, at location x can thus be given as

$$\pi(x) = p(x)H(M(x), L(x)) - (r(x)L(x) + kM(x)). \quad (6)$$

The first term on the right-hand side of Eq. (6) is the total revenue from housing rents, and the final two terms in the bracket are the land rent cost and the capital cost, respectively. With the assumption of the constant returns-to-scale housing production function, Eq. (6) can be converted to

$$\pi(x) = L(x) \left(p(x)H(M(x)/L(x), 1) - r(x) - k \frac{M(x)}{L(x)} \right). \quad (7)$$

Let $S(x) = M(x)/L(x)$. It represents the capital investment per unit of land area at location x , namely, the capital investment intensity. Eq. (7) can then be rewritten as

$$\pi(x) = L(x)(p(x)h(S(x)) - r(x) - kS(x)), \quad (8)$$

where $h(S(x)) = H(S(x), 1)$, i.e., the housing output per unit of land area at location x . Thus, maximizing the net profit at location x in Eq. (8) is equivalent to maximizing the net profit of unit land input, expressed as

$$\max_S \pi(x) = p(x)h(S(x)) - r(x) - kS(x). \quad (9)$$

The first-order optimality condition of the maximization problem (9) yields

$$\frac{\partial \pi}{\partial S} = p(x)h'(S) - k = 0. \quad (10)$$

Substituting Eq. (3) into Eq. (10) yields the optimal capital investment intensity S as a function of location x and the common utility u , as follows.

$$S(x) = S(x, u). \quad (11)$$

The residential density, denoted as $n(x)$, at location x can thus be calculated by

$$n(x) = \frac{h(S(x, u))}{g(x, u)}. \quad (12)$$

Note that under perfect competition, the property developers earn zero profit. Thus, setting $\pi(x) = 0$ yields the land rental price $r(x)$ as a function of location x and common utility u , as follows.

$$r(x) = r(x, u). \quad (13)$$

So far, the model gives rise to the functions $p(x, u)$, $g(x, u)$, $z(x, u)$, $S(x, u)$, $n(x, u)$, and $r(x, u)$, which are all functions of utility u .

Finally, we define the housing demand-supply equilibrium conditions. On one hand, the equilibrium rent per unit of land area devoted to housing at the city boundary equals the exogenous agricultural rent or the opportunity cost of the land; that is,

$$r(B, u) = r_a, \quad (14)$$

where r_a is the constant agricultural rent, and B is the city size.

On the other hand, the housing demand-supply equilibrium requires that all households fit exactly inside the city boundary, i.e.,

$$\int_0^B 2\pi n(x, u)xdx = N, \quad (15)$$

where N is the city's population size.

There are unknown variables B and u (or N), depending on whether the city is “open” or “closed”. For a closed city, the city’s population size N is fixed exogenously, whereas the utility u and city size B are determined endogenously by Eqs. (14) and (15). For an open city, the value of u is given exogenously, which is the base utility level of the economy, whereas the population size N and city size B are determined endogenously by Eqs. (14) and (15).

Some Extensions of the Classic Mono-centric City Model

The classic mono-centric city model has been extended in numerous ways, such as by considering traffic congestion effects, competition between transport modes, heterogeneity of households in terms of income level, asymmetric urban structure, and polycentric urban structure.

In the Presence of Traffic Congestion

Commuting cost plays an important role in shaping the urban spatial structure. The classic mono-centric city model assumes that the commuting cost depends only on the distance between the residential location and the workplace, and is thus independent of the actual residential density or travel demand. That’s to say, there is no traffic congestion in the urban system. The congestion-free assumption may cause a significant bias in the prediction capability of the model and thus restricts its applications in practice.

In order to consider the congestion effects, transportation cost at any location depends not only on the distance traveled, but also on the density of traffic from that location to the CBD. Let $N(x)$ be the number of residents living beyond location x , which can be determined by integrating the residential density from location x to the city boundary. Suppose that there is one commuter per household, and thus $N(x)$ is the total number of commuters traversing location x . Let $L_T(x)$ be the amount of land devoted to transport usage around location x . Accordingly, the marginal travel time per unit of distance at location x can be calculated by a function of the traffic-land ratio, $N(x)/L_T(x)$. The annual travel cost of each household at location x , denoted by $T(x)$, can thus be calculated by

$$T(x) = \int_0^x a \left(\frac{N(w)}{L_T(w)} \right)^m dw, \quad (16)$$

where a and m are positive parameters, which can be calibrated by survey data.

Mode Choice

The classic mono-centric city model involves an auto-only urban system, and the interaction and substitution effects between auto and transit modes (e.g., bus) are usually ignored. In reality, auto and bus transit usually share the same roadway. They have impacts on each other and thus on the level of congestion in the urban system. The congestion interaction between them directly affects the cost of travel by a particular mode and thus the travelers’ mode choices, which further influence service strategy of the transit operator (e.g., frequency and/or fare). Conversely, a change in the transit service frequency and/or fare can cause a change in the modal split of auto and bus. As a result, the level of traffic congestion on the road also changes. It is, therefore, of great importance to incorporate congestion interaction and substitution effects between modes and the mode choice behavior of travelers in the city models (Li et al., 2013; Li and Wang, 2018). One can adopt Wardrop’s user equilibrium or multinomial logit model to model the travelers’ mode choice behavior.

Heterogeneous Households in Terms of Income Level

The classic urban model usually assumed that all the households in the city system are homogenous in terms of income level. However, income heterogeneity is universal in reality, leading to a strong effect on the bidding price for housing, and thus the household residential distribution. It has currently been observed in some large cities across the world that high-income households and low-income households are spatially segregated, which is referred to as the residential segregation phenomenon. For example, high-income households in China prefer to reside in the urban central areas, whereas low-income households tend to live in the suburban areas. However, a reverse residential pattern (i.e., high-income households reside in the suburbs, whereas low-income households reside in urban central areas) occurs in some other countries or areas, such as Detroit, the United States (Brueckner et al., 1999). Accordingly, the homogeneity assumption may cause a significant bias in the prediction capability of the model in the urban spatial structure. The effects of income heterogeneity on the household residential location choices and the urban spatial structure should thus be considered. A recent study has identified the conditions under which either the rich or the poor live in the urban central area while the other prefer the suburb (Li and Peng, 2016). The study has also shown that a high emission tax can drive the poor to migrate from suburbs to urban central areas, and the rich to migrate from urban central areas to suburbs.

Figure 1 An asymmetric city with radial major roads.

Asymmetric Urban Structure

In the literature, the urban spatial equilibrium analysis of a mono-centric city usually assumed that the urban system was a perfectly divisible dense system consisting of an infinite number of radial roads. That is to say, they mainly focused on a symmetric urban structure with evenly distributed radial roads along mono-centric circular city. A more realistic case is to relax the “symmetry” assumption to consider an asymmetric two-dimensional mono-centric city with a small number of radial major roads (e.g., these radial major roads are not uniformly distributed along the city and/or have different capacities) connecting the CBD to its suburban areas, as shown in [Fig. 1](#). In such an urban system, a ring-radial travel method can be applied, namely, commuters first travel along a minor ring road to get to a radial major road, and then proceed along the radial major road to reach the city center ([Li et al., 2013](#)). Referring to [Fig. 1](#), two adjacent alternative radial major roads in the two-dimensional mono-centric city compete for travel demand. A watershed boundary (or market area boundary) exists that divides the area between these adjacent radial roads into two sub-areas. When an equilibrium state is reached, no commuter in the city has an incentive to change his/her choice of radial major road when traveling to the CBD. This means that the cost of traveling from a point on the boundary contour to the CBD using two adjacent radial roads is identical. It should be pointed out that the traffic flows on the radial major roads are interdependent: an increase in the flow on one radial road leads to a decrease in the flow on another. In addition, the single-mode asymmetric mono-centric city model can be extended to a multi-mode scenario ([Li and Wang, 2018](#)).

Polycentric City

Since Alonso (1964), Muth (1969), and Mills’s (1972) theory of urban spatial structure, the mono-centric city models have become widely accepted in urban economics. The mono-centric city models assume that all job opportunities cluster in a CBD area. The impractical assumption of a single employment center has suffered some criticisms. Polycentric models have been developed since the 1970s. The models focus on how workers decide where to live and work and the resulting spatial patterns of land and housing rents, population densities and commuting regions ([Anas and Kim, 1996](#)). The polycentrism favors employment decentralization and polycentric development, which may improve commuting patterns by shortening individual commuting distances and time, and the polycentric city could promote spatial equity through increased opportunities to access jobs nearby housing leading to positive effects on productivity, livability and efficiency. In the polycentric city models, the locations of the employment centers may be exogenously given or endogenously determined, and the workplace for a two-worker household may be situated at one or multiple locations. The polycentric city models can also be extended to investigate the competition and collaboration between cities in an urban agglomeration, and between urban agglomerations, particularly in the context of China’s Belt and Road Initiative.

Policy Evaluation

In an urban system, there are multiple stakeholders, for example, the government, property developers, and households. A strong interaction exists between urban policies implemented and the urban spatial structure. For example, implementation of a transport policy has a direct impact on location accessibility and thus individuals’ commuting cost, which in turn affects households’ residential location choices and property developers’ housing production, which further affects the urban spatial structure in terms of residential distribution and housing market (housing rental prices and housing space). Inversely, urban land use pattern, which involves the spatial distribution of residents over the city through the housing supply-demand balance, can govern the travel

Figure 2 Interactions among stakeholders in urban systems.

demand distribution across the city, which affects the design and optimization of urban policies for achieving sustainable urban development. The interactions among the government, property developers, and households are shown in Fig. 2. Generally, urban policies include supply-side policies (e.g., infrastructure investment) and demand-side policies (e.g., congested road/parking pricing, commuting subsidies), which are discussed in the following sections.

Infrastructure Investment

In response to the rapid growth in the number of motorized vehicles and traffic congestion, local authorities have launched a number of transportation infrastructure investment projects to mitigate auto-related problems (e.g., road traffic congestion, parking congestion, and environmental issues). Some typical infrastructure investment strategies include: (1) constructing new radial major roads that connect the city's CBD to its suburban areas (Li et al., 2013) and/or new parking facilities (e.g., parking garages, on-street parking lots); (2) implementing integrated rail and railway station property development, in which such variables as rail line length, number and spacing of stations, headway, and fare can be optimized (Li et al., 2012); (3) introducing transit-oriented development (TOD) project (Peng et al., 2017), which refers to medium- and high-density housing along with complementary public uses, jobs, retail, and services in mixed-use development around transit stations. In the TOD projects, there is a need to determine the optimal location, number and size of the TOD zones on a rail transit line such that the TOD investment projects are economically viable and cost-effective from an input-output perspective. The infrastructure investment can cause changes in the urban spatial pattern in terms of the residential location choices, property values, and housing market. These externality effects should be incorporated in the infrastructure investment decisions.

Congestion Pricing

The under-pricing of auto travel is regarded as an important source of market distortion (or failure) and resource waste in urban transportation systems. As a result, auto is overused and road/parking congestion is becoming an increasingly serious problem, particularly in densely populated large cities, such as Beijing and Hong Kong. Congestion pricing has been widely proposed as a feasible solution to the growing problem of traffic congestion because of its potential to internalize congestion and environmental externalities and correct market distortion (Verhoef, 2005; Chen et al., 2018). The ongoing rapid development of information and communication technologies has aided and supported the practical implementation of congestion pricing schemes.

Congestion pricing schemes include the first-best and second-best schemes. The first-best scheme is also referred to as social optimum scheme or marginal cost pricing scheme. In the first-best scheme, the congestion tolls equal the congestion externalities that an additional auto trip imposes on the existing vehicles in this system. There are various second-best tolling schemes, such as cordon-based tolling scheme (i.e., each auto user passing through a specified cordon is charged a fixed toll) and distance-based tolling scheme (i.e., toll is proportional to the distance traveled). Tradable credit scheme, as a variation of congestion pricing schemes, has recently received considerable attention. In the tradable credit scheme, the authorities initially allocate the credits to all households in the urban system, and the households pay a certain amount of credits according to the externalities they generate during the course of their trips.

It has been seen that congestion pricing has an effect on the urban form through changing household residential distribution and housing market. Such effect is closely related to the redistribution schemes of the congestion tolls. For example, the congestion tolls may be redistributed to the urban residents or kept by the authority (e.g., the government). With different redistribution schemes, congestion toll may lead to a more compact or a more decentralized urban structure.

Commuting Subsidies

Commuting subsidy policies have been implemented in many countries in different forms, such as work-related deductions (e.g., France or Italy), a single allowance for commuters (e.g., Germany, the Netherlands, Denmark, Switzerland), or income-dependent tax credits (e.g., Japan) (Potter et al., 2006). Commuting subsidies aim to improve efficiency in the labor market by encouraging workers to increase their radius of job search and to commute further for a better match. From a perspective of social welfare, encouraging people to increase their job search radius in order to find better matches can be seen as positive, but longer commutes also entail negative externalities. The social welfare depends on the trade-off between better matches and the negative externalities.

Regarding the topic of commuting subsidies, there are many issues that deserve to be studied. For example, whether commuting costs/reimbursements should be made deductible/exempt from the income tax, and if so, whether full or only partial costs should be deducted; how to design a commuting subsidy scheme to reach an efficient level of job search and commuting; how to redistribute the commuting subsidies by vehicle ownership, income, or commuting distance, and what are the re-distributional effects of the commuting subsidies on the urban system.

Introduction

Value of Time in Freight Transport: What is it?

The value of time (VOT) in freight transport is the marginal rate of substitution between the time it takes to transport goods on the one hand and money on the other hand. A related concept is the value of transport time savings (VTTS) in freight transport, which is the amount of money a firm or society, is willing to pay to save one unit of transport time (reduce the transport time by one unit). Even though these concepts are called “values” transport time actually represents a disutility or cost: more transport time (for the same goods flows) is a negative and when time has a higher VOT, this negative impact is increased. In this context, one could also talk about the cost of transport time increases (CTTI). There is value and there are benefits in reducing transport time.

Why do Transport Time Savings Have a Value?

Reductions in transport time in freight can lead to different benefits for different decision-makers in freight transport (Table 1). The transport itself is for a large part carried out by specialized firms, the carriers that have their own (or sometimes leased) transport vehicles and staff to drive and supervise these vehicles. If the transport time would be reduced (e.g., as a result of a new road link), the vehicles and drivers would be used for a shorter duration, and the carriers could either perform more transport assignments or do the same assignment with fewer vehicles and staff. In the short run the possibilities or benefit from this might be limited, but in the long run they can reschedule their services and production factors. So, the long-term gain of a time saving could be as high as the sum of the time-related transport costs for that amount of time. These are often taken to be all the transport costs except the purely distance-related costs (such as fuel costs, energy costs, and user charges for the use of rail infrastructure).

The shipping firms (producers or traders of commodities) want to send their products to their clients and so they have a demand for transport services. A part of this demand might be supplied by the shippers themselves (this is called own account transport), but in most cases the transport is contracted out to carrier firms or intermediaries, for which the shipper pays an agreed rate. Benefits that a carrier gets when time is reduced may be transferred to the shippers through reductions in the price of transport (depending on the market conditions). But even when no transport cost benefits are passed on to the shipper, shippers can have a benefit from transport time reductions: the fact that the goods themselves are away for a shorter time can:

- lead to a reduction in the interest costs on the capital invested in the goods during the time that the goods are transported, and to
- the reduction in the value of perishable goods during transit, but also in the possibility that the production process is disrupted by missing inputs or that customers cannot be supplied due to lack of stock.

Shippers with own account transport can be expected to see both the vehicle and staff benefits as well as the cargo-related benefits.

The carrier's VOT typically relates to the driver and the transport equipment; drivers are paid wages and the equipment has to be depreciated (or their lease paid). A carrier incurs these costs irrespective of the type of goods being carried (or even whether the vehicle is loaded)—these costs are not commodity-specific.

The specific VOT of the shippers on the other hand relates to the contents of the shipment, the market value of the goods, their depreciation, their tendency to degrade, the risk of theft, and also to the wider logistics system of which the transport operation is a part.

Sometimes, not the senders but the receivers of the goods are responsible for the transport and already considered the owners of the goods during the transport. In such cases these receiving firms will be the ones where the cargo-related benefits of time savings may accrue.

Table 1 Different benefits from time savings for different decision-makers in freight transport

	<i>Benefits related to the cargo</i>	<i>Benefits related to the vehicles and staff (transport costs)</i>
Carrier	Not relevant	Relevant
Own account shipper	Relevant	Relevant
Shipper that contract out	Relevant	Not relevant

For society, both types of benefits (cargo-related and transport cost related) matter, so in a societal evaluation, like a social cost-benefit analysis (SCBA), both types of benefits should be taken into account. This does not necessarily imply that both should be included in the transport time benefits through the VTTS, but this is definitely one possibility. We will come back to the use of freight VTTS in SCBA later in this chapter.

What is it Used for?

Similarly to the VOT in passenger transport, the freight VOT is used for two different purposes. On the one hand, the freight and the passenger VTTS are inputs into the SCBA of infrastructure projects, making it possible to compare time savings against investment cost and other effects of the project. On the other hand, both the passenger and freight transport VOTs are also used in traffic forecasting models to calculate the “generalized cost,” an important explanatory variable in the model, defined as a linear combination of travel time and cost. Values of time for SCBA and modeling may differ in the treatment of taxes. In the further discussions, we focus on the use of the freight VTTS in SCBA.

Regarding the use of the freight VTTS in SCBA, we can say that there are two distinct “schools” or approaches in terms of what is included in the VTTS (**Fig. 1**). The first school defines VTTS as the cargo component only ([Vierth, 2013](#)) and includes impacts of projects on staff and vehicle time saved in the SCBA through the transport cost savings (together with the distance-based cost, including energy and infrastructure use charges, that should not be in the VTTS in either approach).

The second group uses a VTTS that contains both the cargo and the transport services component ([de Jong et al., 2014](#)); in the SCBA all time benefits in freight are expressed through the VTTS and transport costs benefits only refer to reductions in the trip lengths (if any).

There is no absolute truth in the choice between approaches A and B. Both methods can be carried out in such a way that no benefits are forgotten and no benefits are counted twice. If VTTS is the cargo component only, one should, in evaluating time saving projects, take care not to forget reducing the time dependent transport costs (as part of the cost savings). If both components are in the VTTS one should take care not to double count the distance-dependent transport cost. Approach A with a low VTTS is used in practice in for instance Sweden and Approach B with a high VTTS in the Netherlands.

Methods Used to Determine the Freight VTTS

The methods to find proper freight VTTS for project appraisal or forecasting can be classified into factor-cost methods and modeling studies.

Factor Costs

Factor cost refers to the cost of all input factors into some production process, in this case the production of freight transport services. The factor-cost method in VTTS research tries to find the cost of the input factors that will be saved when transport time is saved. A reduction in transport time could release production factors (e.g., labor, vehicles), which could be used in other shipments. These

Approach A	Approach B
Time savings:	Time savings:
Cargo time saved	Cargo time saved Staff time saved Vehicle time saved
VTTS	VTTS
Transport cost savings:	Transport cost savings:
Distance cost saved Staff cost saved Vehicle cost saved	Distance cost saved

Figure 1 Approaches to time/cost benefits in SCBA.

cost reductions can be calculated using data on wages and vehicle prices, taxes, insurances, and maintenance. A more difficult issue is whether overheads and non-transport inventory and logistic cost should be included. This could be analyzed using the other type of method, that is, the modeling studies. Some researchers have argued that not all labor cost should be used in the VTTS, since some of the time gains cannot be used productively. This too can be analyzed by modeling decisions in freight transport and focusing on the implied time-cost trade-offs. The issue of which cost items to include also depends on the time horizon: in the long run, more items will be time-dependent and the long VTTS will be higher than the short run one.

When applying the factor cost method, the researcher also has to decide which costs will be attributed to the impact of transport time itself and which costs to the impact of transport time reliability. In a model it might be possible to separate out the cost related to the average transport time on the one hand and the extra cost of delivering too late (too early) or the cost on the variability on the other hand. In a factor cost calculation that uses a simple transport cost function, it is very difficult to separate out the impact of transport time variability. However, if one would use a full logistics cost function, both the VTTS and the VTTV (value of transport time variability) can be calculated as the derivatives to transport time and variability (expressed as the standard deviation or variance of transport time). This full logistics costs function would then include components for the value of the goods, the deterioration of the goods, and the cost of keeping a safety stock (as a function of, among other things, transport time variability).

Modeling Studies

The modeling studies that seek to determine the VTTS can first of all be distinguished according to the type of data that is used in the modeling:

- revealed preference (RP) studies;
- stated preference (SP) studies.

There have also been a few joint RP/SP models in freight transport.

The general definition of RP studies is that they use data on observed real-world behavior. In freight transport these are data on the choices that shippers, carriers, intermediaries, or drivers actually made in practice. In SP studies, the researcher defines experimental choice alternatives. These are presented to the respondents and they are asked to make a choice or give their most preferred alternative. The researcher who wants to model VTTS using RP data first has to look for real world choice situations where these decision-makers are trading off time against cost. Some examples of such situations might be:

- the choice of mode between a fast and expensive mode and a slower and cheaper mode;
- the choice of route between a fast toll route and a congested toll-free route.

The VTTS in the literature that come from RP data are mostly based on mode choice data (e.g., road versus rail, rail versus inland waterways), which could be (Tavasszy and de Jong, 2014) aggregate (transport flows by commodity type between zones), or disaggregate (individual shipments between firms). The inputs on transport time and costs for the chosen and unchosen modes usually come from transport networks. Both in aggregate and disaggregate RP studies, researchers often have to deal with the high degree of correlation between transport time and cost, which makes it difficult to estimate significant coefficients for both attributes. In an SP experiment, the researcher can control the correlation, so this problem can be avoided. Nevertheless, there have been various RP studies where it proved possible to estimate both time and cost coefficients (e.g., the Dutch BasGoed model). Aggregate models are much more common in freight transport than disaggregate models since there are not many data sources on actual choices (e.g., mode and route choice) at the individual shipment level; there are many more travel surveys in passenger transport than shipper surveys in freight.

RP-based VTTS are usually the by-product of the development of a national or regional freight transport forecasting study. The national studies that have been undertaken in recent decades with the explicit aim of determining VTTS have almost all been SP studies (e.g., in Norway, the Netherlands, Germany, Belgium, UK, Australia). In an SP freight VTTS study, decision-makers (in practice almost exclusively shippers or carriers) are asked to elicit their preferences for hypothetical alternatives, which usually refer to shipments/transportations they have been involved in, and which will have different attribute levels for transport time and cost, and possibly also for other attributes of the shipment. In practice, the RP-based values often differ from the SP ones, but a recent meta-analysis of freight VTTS (Binsuwardan et al., 2019) has not found a significant difference between SP and RP values.

These SP experiments can be about the choice of mode or route, as in RP. However, for VTTS research favorable experience has been obtained in abstract time versus cost experiments in which all alternatives that are presented refer to the same mode and the same route. In an abstract time versus cost experiment the alternatives have different scores on travel time, travel cost, and possibly other attributes, but the alternatives are not given a mode or route label, such as "rail transport" or "motorway with toll."

A specific problem in finding the VTTS for freight, as opposed to the passenger VTTS, is that some of the information in goods transport, especially on transport cost and logistic cost, may be commercially sensitive. Firms in freight transport may be reluctant to share this information with client, competitors, and the public. SP data has some advantages in the case of freight transport modeling, in particular as it may be possible to obtain data (e.g., on costs and rates) which would be difficult to acquire by other methods.

A difficult issue in SP surveys on freight service valuation is who to interview. The best advice probably is to interview shippers (that contract transport out) to obtain estimates of the cargo VTTS and carriers to get the transport cost VTTS. However, when doing

this, it is important to make clear to the shippers and carriers which considerations they could take in mind and which aspects we are asking from other decision-makers.

For models that are built for the sole purpose of deriving monetary valuations, the mixed logit specification is nowadays the prevalent type of model. Among models that are estimated for use as forecasting models, multinomial, and nested logit models are dominant. This is caused by the fact that forecasting models are run many times after they have been estimated (and this would take very long with mixed logit because of the repeated simulation that is involved) whereas for a monetary valuation just doing model estimation is sufficient.

There is considerable heterogeneity in passenger transport, but even more in freight transport. The size of the shipment may vary from a small parcel to the contents of a bulk vessel. The value of a truckload of waste material is vastly different from that of the contents of a full money transport vehicle. One might then conclude that the value of freight travel time savings is so heterogeneous that it cannot be established, but this would go too far. Especially the transport costs component of the VTTS, which usually is by far the largest component, is largely independent of the type of goods, as was argued above. Furthermore, heterogeneity in the value of the cargo-related component can be taken into account by applying a proper segmentation (e.g., by mode, type of good). Also, it is important to use proper scaling for the VTTS (e.g., using a value for a typical shipment size or a value per ton).

Some Outcomes for the VTTS in Freight

Table 2 contains a new summary of values from the literature that refer to road and rail (studies that include other modes than road and rail are very scarce). It only used studies that yield values expressed per ton or that can be expressed as such. We explicitly make the distinction between values for the goods (cargo) component, the transport services (costs) component, and the sum of both components. All the values that we used here come from Europe.

In terms of numerical values for the VTTS, the picture that emerges from **Table 2** is that in almost all studies, the value of the goods component in the VTTS is rather low relative to the values found for the sum of both components. If we take the example of rail transport, the value of the cargo component is between 0 and 0.7 euro/ton/hour for all goods together, with a central value of about 0.3, whereas the values found for the sum of both components are around 2.7 euro/ton/hour. For road the cargo component is between 0 and 2.5 euro/ton/hour, with a central value of around 1 euro. The sum of both components is about 7 euro/ton/hour. Large values for the goods component of the VTTS are only found for specific high-value commodities (e.g., automotive, vehicles and machines, container, finished goods, and especially express goods). For both road and rail transport, the goods component appears to be the minor component in the VTTS.

The range that we obtain in **Table 2** for the cargo component is relatively large. Apart from methodological differences between studies and in income levels between countries, this can be explained by variation between commodity types. The total VTTS for rail per ton (2.7) is clearly lower than for road (which amounts to about 7 euro/ton).

A key result is that the transport service component of the VTTS will be (especially in the long run) more or less equal to the cost of producing the transport services per hour (the sum of the staff and vehicle cost per hour including overheads, but not including distance-dependent cost). It is therefore not really needed to do new SP research in some country to get these values, one can simply use the factor costs method to find this component. This component will hardly or not varies between commodity types, but it will vary between modes.

Table 2 Value of transport time savings (VTTS) in goods transport (in 2010 euro/ton/hour)

<i>Publication</i>	<i>Country</i>	<i>Data</i>	<i>Method</i>	<i>VTTS</i>
<i>The goods (cargo) component in the VTTS:</i>				
Publications between 2000 and 2015	Finland, Italy, Switzerland, Belgium, Denmark, Sweden, Switzerland, Norway, The Netherlands, France, Germany and the UK	SP, with one or two RP studies	Mainly MNL and mixed logit, some ordered probit, nested logit and weighted regression MNL	0–0.7 for rail; central value: 0.3 0–2.5 for road; central value: 1
<i>The transport services (costs) component in the VTTS:</i>				
Publication from 2013	The Netherlands	Transport cost functions	Factor cost	2.4 for rail 6.3 for road
<i>Both components in the VTTS:</i>				
Publication from 2013	The Netherlands	Transport cost functions and SP	Factor cost and MNL models	2.7 for rail 7.0 for road

For passenger transport, so many VTTS are available that various meta-regressions have been carried out, that try to explain the VTTS obtained from attributes of the respective countries and study methods used. For freight transport, the number of VTTS available is somewhere near the margin of what is minimally needed for a meta-regression.

The cargo component of the VTTS cannot so straightforwardly be derived from the factor cost. If possible, specific SP surveys are recommended. If these are not possible, one could use for the cargo component of the VTTS in freight a fraction, for example, 10%–20%, of the full transport cost (including time- and distance-dependent cost); this fraction is based on the results from the Netherlands (de Jong et al., 2014). Variation between commodity types (which one would expect for the cargo component) can be derived from the results of recent French (CGSP, 2013), German (BVU and TNS Infratest, 2014), or UK studies (Fowkes, 2006) on VTTS.

Conclusions on the Value of Time in Freight Transport

The value of transport time savings (VTTS) is one of the most used and researched concepts in transport economics. Most research refers to the VTTS in passenger transport, but the freight VTTS is also often used in the social cost-benefit analysis (SCBA) of transport projects (some projects even especially cater for freight transport benefits) and in transport forecasting models.

As regards the freight VTTS it is important to distinguish between the transport costs component and the goods component. The former is usually more important and can be derived from SP interviews with carriers, but the long run value can also be obtained by calculating the non-distance-related transport costs per hour. The cargo component usually comes from SP interviews with shippers, which can also contain transport time reliability as an attribute so that both monetary values can be derived from the same study.

In SCBA, the VTTS can be defined as only this cargo component, with the transport costs component being included in transport cost savings. Another approach, different but equally valid, is to include both components in the VTTS and therefore in the transport time benefits, so that the transport costs savings only refer to reductions in the distance-related costs.

Economics of Urban Freight Transport

The majority of EU population (74%) lives in city, towns and suburbs, and this number is expected to increase in the next years (UN, 2019). Urbanisation implies that people gather in a place, remote from sources of food, consumer products, and waste disposal opportunities (Ogden, 1992). Under this respect, freight transport demand is *derived*, but *essential*.

Urban freight transport (UFT), urban logistics, last mile logistics, city logistics are all different terms referring to the processes connected to freight movement at the urban level. UFT has several definition, one of the most cited being the one by Taniguchi et al. (1999, p. 17): “the process for totally optimising the logistics and transport activities by private companies in urban areas while considering the traffic environment, the traffic congestion and energy consumption within the framework of a market economy”. UFT is a complex world characterized by scarce knowledge and heterogeneous stakeholders, interacting and often competing: some of them (shippers, transport providers, retailers) aiming more at *efficiency* while some others (citizens, consumers, policy-makers) at *sustainability* (Gatta et al., 2017). In order to understand the economics of urban freight, it is useful to recall basic economic theory concepts and then apply them to UFT (Button and Pearman, 1981).

Economics essentially focuses on how stakeholders make choices; specifically, how they allocate scarce resources to alternative forms of production, how they distribute production to consumption between groups, how they choose between present and future consumption.

Production is linked to supply, while consumption to demand. Relevant information and understanding derive from a formal analysis of supply and demand interaction. Consumer behaviour relates to demand, while to study supply one needs to focus on costs. Firm behaviour is interlinked both with market type and structure. The overall purpose being the investigation of social welfare and its relationship with production, consumption and exchange of goods and services.

Supply, demand, market structures and stakeholders’ objectives are extremely heterogeneous when one looks close enough to UFT. In fact, there are different market characteristics even when, at a first glimpse, they might look very similar. The market power a generic transport provider has in UFT (inferred by the average number of employees) is much lower with respect to one operating in the building sector. Shippers are interested in getting the goods safely delivered to their customers in the city, while transport providers would like to minimize their operating costs, and retailers are interested in getting the goods delivered on time to their shop. While this is typically true, its level of representativeness might drastically change in different supply chains. What is true for frozen food might be less true for fresh ones, just to mention two apparently similar types of delivery services. These characteristics are reflected in the high level of market segmentation, customers’ preferences (rich and poor) and suppliers’ cost functions (e-tailers or omni-channel retailers). Furthermore, this substantial level of heterogeneity is further reinforced when considering other city characteristics, such as: 1) customer density (people/km²), 2) land prices, 3) road (time windows) or 4) other (supermarket dimension) regulations in place, etc.

In conclusion, one could say that the standard economic theory, no doubt, also applies to UFT; however, its practical use is much hampered both by the level of heterogeneity in this market, the complexity and articulation of market relationship among these actors and the non-negligible role interaction effects play in this specific sector. This points to the need of a public intervention to regulate UFT, especially because of the negative externalities it produces at a city level. Next section will present an overview of UFT externalities and the need for UFT planning to guarantee efficiency and sustainability of freight deliveries.

The Need for UFT Planning to Foster Sustainability

UFT Externalities

An efficient distribution system is of major importance for the competitiveness of a city and is, in itself, an important element of the urban economy (Browne and Allen, 1999). However, various negative externalities show that the effects of continued growth in freight transport is not sustainable in the long term, impacting on (1) planet, (2) people, and (3) profit. The extant freight transport and, in particular, UFT negatively impacts the planet because of the:

- pollutant emissions, including global (e.g. CO₂) and local pollutants (e.g. CO, NO_x, PM₁₀, VOC_s);
- use of non-renewable natural resources (e.g. fossil-fuel);
- waste products (e.g. tyres, oil and other materials).

Current UFT also negatively impacts on people due to the:

- physical consequences of pollutant emissions on public health (e.g. death, illness);
- injuries and death resulting from traffic accidents;
- increase in nuisance (e.g. noise disturbance, visual intrusion, stench, and vibration);
- reduction in quality of life elements (e.g. loss of greenfield sites and open spaces in urban areas due to transport infrastructure, decrease of attractiveness of a city centre);
- damage to buildings and infrastructure (e.g. Coliseum in the city of Rome).

The negative impacts UFT provokes on profit are ascribable to the:

- inefficiency and waste of resources;
- decrease in journey reliability and delivery punctuality, potentially resulting in lower quality of services to consumers;
- decrease in economic development (e.g. reduced market areas);
- congestion and decreasing city accessibility.

In order to have an idea of the effects produced by UFT, Table 1 summarizes some data taken from CIVITAS (2015).

Private and Public Coordination

UFT affects the community as a whole. However, most freight activity occurs outside of the public realm. The public sector is responsible for planning, owning, and maintaining infrastructure and to create the economic framework in which private entities operate by issuing various regulations. In other words, it is responsible for regulating/pricing UFT to optimize the allocation of scarce urban space and the externalities from transport. The private sector, in turn, largely makes operating decisions as well as company-specific investment decisions (National Academies of Sciences, Engineering, and Medicine, 2009). Public sector decision-making regarding UFT can influence or constrain the course of action and the future of freight transport. It should pay great attention to the many factors linked to competing demands, due to the heterogeneity characterising UFT (National Academies of Sciences, Engineering, and Medicine, 2015). Private sector decision-making is also driven by several factors, influenced by the need of companies to survive in a competitive marketplace, generate a return, and satisfy customers, while operating within a given legal/regulatory framework. Under this respect, public and private decisions overlap and interact in many areas, leading sometimes to cooperation, and other times to conflicts and inefficiencies.

The National Academies of Sciences, Engineering, and Medicine report on “Public and Private Sector Interdependence in Freight Transportation Markets” (2009) focused on projects involving both public and private sectors, deriving some key lessons for successful cooperation between public and private entities. Under this respect, it is important and critical to:

Table 1 Urban freight transport in numbers (retrieved from CIVITAS, 2015)

km travelled	10–15% of total km travelled
GHG emissions	≈ 6% of all transport-related GHG emissions
Workforce employed	2%–5% of the total workforce employed in urban areas
Urban land	3%–5% reserved to logistics activities
Flows	≈ 20–25% of freight_veh/km related to goods leaving urban areas, 40–50% to incoming goods and the remaining to internal flows
Delivery/pick-up per person per day	0.1
Delivery/pick-up per economic activity per week	1
Freight vehicle trips per 1000 persons per day	300–400
Tons per person per year	30–50

- build and maintain communication and cooperation among the many private and public stakeholders;
- educate the public sector on the benefits of freight projects to overcome any opposition;
- be aware of how a joint public and private process works;
- maintain key companies and officials who have undertaken an initiative;
- manage new multijurisdictional freight infrastructure projects through a governing agency with responsibility for the design and construction of the project;
- clearly identify the public and private project benefits to cement the desire for both sides to make a project work;
- make the public sector understand the private requirements for funding and the timing of financial flows to make public–private partnerships work better.

Complexity of Supply Chains

A supply chain consists of a system that includes activities, people, technologies, information and resources targeted at transferring a product or a service from the provider of raw materials to the end customer. In the last years, supply chains have become more complex and dispersed due to ever-lower transportation costs as firms along the chain substitute transport for lower cost inputs and higher product velocity (National Academies of Sciences, Engineering, and Medicine, 2013). Freight traffic is particularly growing in cities for different reasons, namely: (1) decline of inventory holding and increase in both the number/variety of goods sold and express transport services; (2) increase in logistics facilities in large metropolitan cities, since modern supply chains require close proximity to consumer markets and trans-shipment services; (3) warehouses and distribution increasingly decentralized to the periphery of metropolitan areas, which leads to increased truck travelled kilometres.

Since supply chains are highly complex and influenced by many different factors, efforts to change them are challenging. At the urban level, important attributes of a supply chain relate to delivery frequency, time and size, and to the possibility of consolidation with other product supply chains (Danielis et al., 2012).

Supply chain also needs coordination, both in terms of long-terms and short-term contracts among different partners, or vertical coordination. A lack of coordination could lead to inefficiency linked to inaccurate forecast, low capacity utilization, high inventory costs, inadequate customer service, bad quality of service and customer satisfaction.

Understanding the underlying mechanisms of supply chains and adopting a supply chain approach is fundamental to understand how urban freight distribution works and what will be the impact of the various potential urban transport policies.

UFT Planning

Before focusing on how public decisions should be made to foster sustainable and efficient UFT, it can be useful to trace back some fundamental aspects linked to transport planning and policy-making. Under this respect, transport planning has traditionally focused on passenger transport, often neglecting freight issues. This lack of attention can be ascribed to a scarce understanding of freight transport, even when local authorities acknowledge its importance for the local economy (Le Pira et al., 2017b). On the contrary, passenger transport solutions mostly rely on solid knowledge and on widely available data. Passenger and freight transport are also different in terms of stakeholders involved. Stakeholders related to passenger transport typically pertain to the public domain, i.e. public transport users, policy-makers, citizens. Vice versa, freight transport mainly involves the private interests of retailers, shippers and transport providers, determining an imbalance due to their economic interests (Gatta and Marcucci, 2016). Many of the challenges impacting on the freight system (e.g. congestion, land use conflicts, community acceptance) typically arise in metropolitan areas (National Academies of Sciences, Engineering, and Medicine, 2015).

Notwithstanding the evident importance of policy-making and knowledge related to UFT, research and several innovation initiatives have been carried out only in the last years. In particular, several projects have proposed solutions to tackle the problems caused by urban freight deliveries (see, e.g. CIVITAS I, II, PLUS, PLUS II), while others have been devoted to collecting and deploying UFT best practices (see, e.g. BESTUFS I, II, BESTFACT, TIDE, SUGAR). Nevertheless, research is still needed to reduce the lack of knowledge and understanding of UFT processes, commercial dynamics and behaviour, which are among the main obstacles to the achievement of sustainable and efficient UFT (Gatta et al., 2017). Besides, a fair number of UFT-related programmes has been characterised by a non-negligible failure rate. This is mainly attributable to the insufficient commitment from relevant stakeholders, which can be related to a lack of incentives (Le Pira et al., 2017a). Under this respect, it is fundamental to actively involve stakeholders from the beginning of the policy-making process, by making them analyse the problem, assume (if any) responsibilities for negative externalities in the logic of “all breakages must be paid for”, and discuss on possible solutions. By doing this, it is likely that decisions will be stakeholder-driven and, thus, more acceptable. There are different ways to involve stakeholders. For example, Marcucci et al. (2017a) describe a successful initiative based on a new collaborative governance model, where public and private stakeholders are appropriately engaged, which proved to be both efficient and effective, since they all felt involved in decision-making resulting in a specific contract where they undertook to respecting the duties assumed during the negotiation phase. Another example is reported in Gatta et al. (2019a) where an interactive multi-criteria approach is employed to properly plan with stakeholders alternative off-hour delivery solutions.

UFT policies can be classified according to specific issues/problems. This suggests why no easy solution is at hand and cannot be seamlessly employed in different cities/contexts. Additionally, no single policy can address and solve all UFT problems, while an integrated policy package approach is needed (Gatta and Marcucci, 2014).

Under this respect, the planning guide proposed by the National Academies of Sciences, Engineering, and Medicine (2015) is intended to introduce a complete catalogue of UFT initiatives that could be considered by public agencies. Starting from the review of more than 150 references, 54 initiatives were selected and classified into eight major groups, namely: (1) infrastructure management - improve infrastructures to enhance freight mobility and make it adequate to current market needs; (2) parking/loading areas management - plan and design both on-street and off-street parking/loading to increase service efficiency and reduce congestion; (3) vehicle-related strategies - implement technologies and programs, such as emission standards and low-noise deliveries, to reduce negative externalities produced by freight vehicles; (4) traffic management - carry out traffic engineering and control measures to improve traffic conditions; (5) pricing, incentives, and taxation - adopt monetary policy interventions to reach the targets set by the public sector; (6) logistical management - adopt strategies to facilitate cargo consolidation, intelligent transport systems and last-mile practices; (7) freight demand/land use management - modify the nature of freight demand and apply land use policy by both relocating large traffic generators and including freight issues in the urban land use planning process; (8) stakeholder engagement - increase the understanding of freight issues within the public sector and effectively involve the private sector to secure commitments to common solutions. It is worthy of notice that the effectiveness of these strategies depends on the specific context as well as on the mode of implementation and, even more important, that a combination of different strategies in policy packages has much more potential for success.

A first logical distinction is between supply and demand initiatives, the former linked to infrastructure management, the latter to freight demand and land use management. However, one should bear in mind that it is often practically difficult to classify a given action to either supply or demand given the interaction among stakeholders and considering the implications each policy implemented might have.

Another important policy principle is that public sector interventions are only justified when a market failure is preventing the economy from reaching its most efficient outcome. Under this respect, while a well-designed public sector intervention could lead the system to greater economic efficiency, it could also make things worse if there is no market failure, causing a “government failure” (Holguín-Veras et al., 2014). In the specific case of UFT, since market failures are always present, it is thus important to study how the public sector should intervene. When deciding how to address the problem, city agencies must carefully take into account this risk, and consider the potential impacts of the solution. Some examples are related to time-access restrictions for all trucks, which could lead to an increase of both carrier costs and freight traffic externalities (Quak and de Koster, 2009) or zero tolerance policies against parking violations, which may require large enforcement expenses, not always compensated by the benefits in congestion reduction (Holguín-Veras et al., 2014).

In any case, planning for sustainable and efficient UFT should account for behavioural issues and stakeholder engagement processes (Marcucci et al., 2017b). A deep understanding of the behavioural aspects linked to stakeholder decision-making is crucial to define and implement effective policies or solutions, capable of accommodating both private and public objectives. Along this line, Marcucci et al. (2015) investigate, at a strategic level, stakeholders preferences for alternative parking and pricing policies and highlight the need for a collaborative approach between local policy makers and transport providers (e.g. living lab) so to avoid “decide and defend” strategies. Marcucci et al. (2018) propose an advanced user-centred approach to appropriately design gamification and maximize its probability of success in fostering engagement and behaviour change in UFT. Gatta et al. (2019b), explore people acceptance towards public transport-based crowdshipping, one of the most promising logistics solutions dealing with the requirements of the on-demand economy, by performing a joint supply and demand analysis.

Urban freight policies/solutions should, therefore, emerge from a collaborative/participatory approach where new behavioural analyses should complement technical analyses, by considering both solution feasibility and acceptability. This important and understudied topic will be discussed in the chapter on “Behavioural Research in Freight Transport” of the Encyclopedia of Transportation.

Conclusion

Economics of urban freight is multifaceted due to the high level of heterogeneity in this market, the complexity and articulation of market relationship among these actors and the non-negligible role interaction effects play. An efficient distribution system is of major importance for the competitiveness of a city. However, various negative impacts show that the effects of continued growth in freight transport is not sustainable in the long term. Economic efficiency and sustainability of UFT solutions can be guaranteed only via a public intervention and appropriate planning processes. Under this respect, private-public coordination based on a proper stakeholder engagement process is a key issue. It will be effective only if supported by appropriate incentives for stakeholders, who should understand and bear (if any) responsibility for the negative UFT externalities produced. Besides, technical and behavioural analyses, together with a good knowledge of supply chains at a city level and of the variety of initiatives that one could adopt, are fundamental to plan for sustainable and efficient UFT.

Acknowledgment

We would like to thank all those who have collaborated in the activities performed by the Transport Research Lab at Roma Tre University (TRELab – www.trelab.it) that supported most of the research at the basis of the present paper.

Biographies

Edoardo Marcucci is Full Professor of Transport Economics at both Molde University College and Roma Tre University, where he is co-Director of *Transport Research Lab*. He is currently co-Editor in Chief of Research in Transportation Economics. Author of several articles published in international top-journals, his research interests mainly focus on urban freight distribution, stated preference, discrete choice modeling, and interaction effects in group decision making. He has been involved in several international, national research projects and evaluation committees.

Valerio Gatta is Researcher of Transport Economics and co-Director of *Transport Research Lab* at Roma Tre University. He has an extensive research experience in innovative transport solutions, especially in urban freight, linked to decision making processes and sustainability, with particular reference to stated preference survey designs and discrete choice modelling techniques. Advanced methods and models for policy acceptability and behaviour change analysis are at the core of his academic path.

Michela Le Pira is Researcher of Transport Planning at the University of Catania (Italy). She holds a PhD in Transport Engineering. As a PhD student, she focused on public participation in transport planning supported by agent-based modelling and multi-criteria decision methods. As a Post-doc researcher at University of Roma Tre, she worked on participatory decision-support methods for sustainable urban freight transport policy-making. As a research fellow at the University of Catania, she is currently investigating new mobility services for both passengers and freight.

Introduction

Incentives of various sorts are present everywhere in the transport sector and other industries. They intend to affect behavior on some party so that some action is taken, or an outcome achieved. Incentives will always have the potential to create both positive and negative effects, and an important task is to balance these with respect to moral hazard and information asymmetries. Furthermore, with a public buyer, incentives would try to align the society's marginal cost for some action with the private seller's private marginal cost. In this chapter, incentives related to public transport contracts are discussed, although aspects touched upon here can well be generalized to other contexts.

The point of departure is a buyer-seller relationship of a public transport service. Two parties will be involved in a business relationship ruled by a contract. The buyer will be referred to as the public transport authority (PTA), who wants to maximize social welfare, and the seller as the (profit-maximizing) operator. The discussion will mainly revolve around incentives that are explicitly and on purpose built into the contract to make the operator strive towards some operational or societal target. This is done because the PTA, for example, through competitive tendering has left some control of the traffic over to a private operator. The incentives discussed will also give some monetary consequence; either through the production revenue, or as penalties and rewards. Alternative ways of incentivizing exist, for example, contract termination, contract extension, or a reputational mechanism that affects the operator in future procurements. However, monetary incentives are the focus here. Furthermore, the chapter's focus will not be on more indirect incentives stemming from, for example, the choice of procuring a service, different contractual forms, or the effects institutional settings and regulations can have. Some of these issues are covered in other chapters of this book.

Contracting

The contract terms govern the responsibilities of the parties for service to be run, not seldom up to 10–15 years. Contracts are mostly incomplete in the sense that they do not cover all possible events and scenarios that might occur. The contractual parties' objectives might differ and, not seldom, be in conflict with each other. Put very simply, the PTA is trying to achieve high social welfare, which often relates to some level and definition of service quality, and the operator wants to make profits, meaning it could cut costs by reducing service quality below the PTA's expected level. This means that when the PTA buys a service, it will have a need to affect, or control, the operator to some extent so that its behavior will align with the PTA's objectives. The PTA could do so by stating very detailed in the contract how the operator must run the service. This gives more control, but will also limit the operator's possibilities to operate efficiently, thus risking that the service becomes poor. One could also question, given a detailed contract, the need for the PTA to buy the service altogether as an in-house operator run by the PTA could give more control over the service. However, the PTA have good reason to buy the service from commercial operators as these are often more efficient than public in-house regimes, thus producing more public transport for the same money. By making operators compete for running the service, the PTA can benefit from efficiency gains and innovative pressure created through the competitive environment, in which the commercial operators exist. The task for the PTA is then to incentivize the operator to align with its societal objectives, which could be viewed as a try to maximize social welfare.

Arguably, in contracts where the consequences of an incomplete contract are minor and quality is easy to infer and verify over the contract period, incentives are less important to ensure a good service delivery. However, the more complex the contracting situation and the bigger consequences poor quality has on the service, objectives must be aligned. One or more well-designed incentives is one way of accommodating this.

Objectives and Targets for the Incentive

The PTA must determine what societal objectives are important for the service, and which one(s) the incentive should focus on. One objective could, for example, be a high market share for public transport, high environmental standards, or high service quality. However, these are subjective objectives. The PTA and the operator might not share the definition on what is service quality, or what is *high* service quality, as it can range a wide array of factors: travel time reliability, cleanliness, safeness, brand perception, easiness of use, and much more. Even with a subjective objective, there is a need to formulate a more concrete target for the incentive with levels the operator must fulfill or some focus it should have. An example of the former could be that the operator must complete at least 95% of the departures each month, and an example of the latter is that the PTA establishes a focus for the operator to increase public transport ridership. The target forms the incentive facing the operator and serves as a proxy for the objective, but is sometimes hard to formulate and can risk not serve as a perfect proxy for the objective. Thus, this is a balancing act. Depending on the objective, more than one target could be needed. The target can be defined only by the PTA, or in collaboration with the operator or public transport industry.

The target must be verifiable and possible to monitor, and it must affect the relevant societal objective. Furthermore, it is important to consider what measures the operator can use to reach or affect the target. Preferably, the operator should be able to take as direct measures as possible. If only indirect measures can be used, the PTA cannot expect very good target fulfillment. The PTA must therefore consider what measures it should leave to the operator to affect the service, and thus the target. This could involve letting the operator own the vehicles, be in charge of the traffic supply, or set fares; all depends on the target selected. Many measures might even lie outside the control of both parties, and can thus not necessarily be contracted easily. However, the more control the PTA hands over to the operator, naturally it loses control itself. It is therefore necessary that the PTA is aware of the power it is giving up. For example, would the power of determining supply be left fully to the operator in order to increase ridership, the PTA cannot reduce supply to affect the route network or cope with troubles in public finances. On the other hand, if the operator cannot use some, or any, efficient measures to affect the target, one could question the need and power of the incentive all together. The PTA can have good reason to trust the operator with controlling measures as more efficient planning or innovative solutions could arise, which would benefit the traffic and service quality. Also, the degree of control exhibited by either party is, of course, not binary. One could easily imagine a situation where the parties collaborate on the supply to be run, for example, by letting the PTA define a minimum service supply. But again, this will affect the operator's possibilities to affect the target.

The possibility to predict the future development of a measure, target, or the service as a whole is also important to consider. Predicting, for example, ridership up to 10 years into the future is hard for either party, which causes uncertainty and risk. Therefore, risk should ideally be placed on the actor that is best suited to manage it.

The difficulties in aligning the PTA's and operator's objectives through targets will also depend on the level of trust between the parties. With more trust, the operator will arguably be more inclined to conform more to the PTA's priorities, although probably not fully. That could channel through, for example, better cooperation in planning the traffic or resolving disputes more easily, which could make the incentive design process easier. Less trust would, in contrast, probably involve more detailed contracts and incentives, more adverse effects, and a potentially worse outcome for both parties. Procurement legislation will also restrict how much trust can be utilized in the contract, not the least because of the principle of equal treatment in procurements.

Monetizing and Pricing

The incentive must affect the operator's revenue in some way, or it will not be prioritized. This could be done with varying complexity. Typically, the incentive would affect revenue through the production revenue function, or as a reward or penalty "on top" of the revenue function, and relate to the fulfillment or focus of the target. These could be combined, as well as used separately. However, the way the incentive is monetized will, arguably, not matter for a rational operator as it will calculate the expected value of all matters affecting its profits, which in turn gives the cost of service for the PTA.

The production revenue function, as referred to here, is the revenue from some output to the transport service produced by the operator. A typical contract would contain a combination of a fixed sum, per kilometer, and per hour revenue, and the operator's risk here lying primarily in the cost of running the bus. The revenue function needs, however, not only be linked to supply related output measures, but also to others such as demand-related ones meaning that the revenue components related to supply could be coupled, or entirely replaced, with a revenue per boarding passenger or passenger kilometer. A demand related revenue component could serve as an incentive to increase ridership and help steer toward some societal objective, for example, improving the market share of public transport, but would also impose demand risk on the operator in addition to the production risk. It also illustrates how the production revenue function design can, implicitly, incorporate incentives, and risk, whether or not the PTA is aware of that.

Another way of monetizing an incentive is to put a revenue on top of the production revenue function. Put simply, the incentive can be designed to give the operator a reward (carrot, or bonus) or penalty (stick, or fine). In theory, there should be little difference between a penalty or reward; a fully informed operator will, again, internalize both. However, the selected design could have a signaling effect. Because a negative incentive is like taking away money from the operator when it does not meet the target, it could be regarded as harsher than a reward. A reward could, on the other hand, be perceived as an opportunity for the operator to earn additional money on top of other revenue.

Irrespective of monetizing the incentive through the production revenue function or by a reward/penalty, the incentive must be priced. The PTA could choose the price itself, let the operator bid on the price, or use a combination of the two. The price must not be so low that the operator disregards the incentive. That is, if the incentive does not affect the financial situation for the operator in the contract, it will not steer toward the target. One reason for this could be poor cost-recovery for the measures it needs to use to affect the target. A too high price, on the other hand, could make the operator “care too much” about the target so that other parts of the contract is neglected, causing adverse effects. A very high price might also put the operator in financial difficulties when performing poorly on the target.

Ideally one would want to use the society's valuation of improving/reducing the target with one unit. However, this value is probably hard to infer. But in determining the price of the incentive, the PTA must still consider its marginal valuation with respect to the incentive. Differentiating the price over, for example, time and route might help fulfilling the objective and prioritize activities to the right places, but might also impose risk by making the contract more complex and monitoring more expensive.

Monitoring and Credibility

Monitoring the operator's performance is necessary to measure and verify the incentive and what financial consequences should face the operator. In essence, it is about verifying quality and contract fulfillment of both parties. Arguably, quantitative targets are easier to monitor, and the more concrete these are the more reliable and cheaper the monitoring is likely to be (of course depending on the technological requirements). One downside is, however, as noted earlier, that it is potentially not a good proxy for the societal objective.

Monitoring should be agreed upon before the contract starts. That way, there is no ambiguity in, for example, how measurements are made, how often, and with what technology. This is also an important aspect when choosing the proper target as monitoring should not be more extensive than it needs to with respect to evaluating the fulfilment of the target and the degree of trust between the operator and PTA. With high trust, the PTA might even be able to rely on self-reported information from the operator, or the other way around. One quickly realizes, however, that this creates an information disadvantage for the party that is the receiver of the information, something that might not play out well in the long term if the reporting party at some point in time decides to cheat. Thus, to make sure that both parties honor the contractual agreement, good monitoring is necessary.

Monitoring is often costly. Data collecting equipment, inspections, and administrative work will increase costs and decrease economic efficiency. Furthermore, the less is agreed upon on beforehand, the harder it gets for the PTA to, with credibility, verify performance. However, the technological advancements made until today should give good opportunity to achieve better outcomes on this through more automated (routine-based) solutions, which could also have the potential to lower administrative costs. More routine-based monitoring also gives better transparency on what and how things are measured, as less ambiguity is feeded into the system. It could also be the case that the relevant data for measuring the target is already being collected through passenger counts (e.g., smart card validations) or real-time info, meaning that the monitoring capacity is already in place.

With the monitoring in place comes the task for the PTA to actually pay, or penalize, according to the conditions in the contract. This is a crucial part for making the incentive work. Even with proper monitoring and a clear incentive, for example, that every departure delayed with more than 5 min at its final stop will result in a penalty, conflicting views and situations will arise. The easier ones to resolve are probably those where the cause of the incident is in some control of some of the parties. If a bus breaks down due to bad maintenance by the operator, the delay is caused by the operator who should face the financial consequences. However, many situations are outside the control of the contractual parties. For example, roadworks next to a bus stop is not an uncommon issue and could easily cause delays, especially in urban environments. The delay would here still be on the operator, but it has not been the cause of the delay and could, arguably, not have done anything about it. However, the PTA have not received the quality required and should have the right to act upon that in accordance with the contract. To avoid this situation, the parties could have agreed in the contract that roadworks are not causing penalties for delays, but there exist many similar situations. Again, listing them would quickly become tedious and make monitoring more expensive. Instead, trust between the parties could benefit the situation. One possible scenario, if the PTA for some reason would choose not to levy the financial consequence, is a negotiation process between the parties to resolve the situation. Such negotiations would, however, also risk bringing more ambiguity to the contract relation, and becomes complex if the PTA needs to make similar negotiations with different operators with different levels of trust. The credibility of the PTA, and the incentive, could be at stake. Especially for penalties, the lower the incentive's share of the PTA's total expenses, arguably its motivation for to levy the penalty is lower because of low cost-recovery of the execution. A paradoxical situation could also arise when an operator is performing badly because of a bad financial situation, and the reduced quality results in high penalties. The PTA wants improvement and enforces the incentive to achieve this, but levying the penalty could risk causing bankruptcy and terminate the service all together. This puts the PTA in a tough spot. Qualification criteria in the awarding process to sort out poor operators in the contract awarding stage can be one way of avoiding such a situation.

Enforcing the contract and being credible is thus essential for the PTA, as it otherwise risks that operators will not respond to the incentive. That would also risk the targets and societal goals set up. This issue is especially important when there is competition for running the service. A PTA that does not fully enforce contracted incentive will impose information asymmetry in the bidding process. Exemplifying with a penalty, because full information amongst all parties is crucial in the bidding stage, less risk-averse operators could leave out parts of its expected penalties and place a lower bid (given a lowest-price auction) if they know that the PTA is reluctant to impose penalties. This could also serve as an entry barrier for operators who are not doing business with the PTA as

they do not have this knowledge thus making them less probable to win the procurement. All this have the potential of reducing competition and lower quality.

Operator Risk Preference and Adverse Effects

The overall design of the incentives will affect both the operator's behavior in the contract, and how it values the contract itself, as noted earlier. The latter is channeled through, in the case of a procurement, the bidding process and will affect the PTA's cost for the contract. When deciding what to bid for the contract, a rational operator will take into consideration the full incentive design and what measures it can use to affect the target. In the case of a penalty incentive, to cope with the expected penalties the operator will incur during the contract term, it will add a risk premium. A reward or a component in the production revenue function would be treated analogously. The greater share of the total revenues, and the more risk or uncertainty, is associated with the incentive, the larger this premium will be.

Contractual relations will create some adverse, and sometimes perverse, effects. Incentives can both accommodate and accelerate these, as well as creating new ones, and an important part of designing contracts lies in minimizing and understanding those effects. However, risk assessment is often a complex and costly task to take on for both parties. For this reason, a very low-powered incentive will probably affect the bid and performance only marginally as the operator is not prepared to make a full-on analysis because that the incentive does not affect profits. This also means the incentive is probably not very powerful either. However, the more profits are affected by the incentive, arguably, the operator will spend more resources on analyzing the risks associated with it. And the more efficient measures the operator can use to affect the incentive, the smaller the relative risk premium is likely to be.

The incentive is intended to add to the operator's behavior. For example, if its revenue is only tied to demand and the operator is paid per boarding passenger, ridership will certainly be a strategic planning variable, albeit not necessarily used in the way the PTA sought to. With a poorly designed incentive, adverse effects could arise whose consequences are not the least dependent on the price and the degrees of freedom the operator has in the contract. For example, if the operator has full control over supply planning, which is not unlikely as supply is an important measure to affect demand, this demand-related incentive could lead to shorter routes and more transfers, which might not favor the overall transport system and reduce social welfare. This was an unfortunate and unforeseen consequence of the initial contract design in Santiago de Chile's Transantiago reform, which was very focused on catering demand. The contract was re-negotiated three times to accommodate the adverse effects of the incentive mechanisms in the contract.

Some incentives are such that high target fulfillment have few apparent negative effects. However, an incentive that on its own serves to improve on specific targets can, in combination with other incentives, create a perverse incentive. For example, it is not uncommon to penalize operators for cancelled departures. Furthermore, to ensure travelers meet an integrated and recognizable public transport system, operators are sometimes penalized when running vehicles with a coloring scheme different from the PTA's. In this case of a contract that uses both incentives, a perverse incentive is created when the penalty for cancelling a departure is smaller than running the departure with a wrong colored vehicle, which is indeed the situation in some Swedish bus contracts. Although not the intention, if a rational operator temporarily have access only to a vehicle that, for some reason, has the wrong coloring, the operator would rather cancel the departure than running it. In this example, the society would have been better off with this departure running, irrespective of bus color. However, it is not necessarily apparent which, if any, of the incentives should be revoked or adjusted. Here, trust between the parties can be beneficial so that similar situations are avoided, or the incentives be adjusted to accommodate the situation.

Summary

This chapter has discussed some important aspects to consider when constructing incentives in public transport contracts. The contractual parties' objectives will not always be aligned, and using incentives is one way of accommodating this discrepancy to achieve good service quality. The level of trust between the parties is important to consider when designing the incentive. The incentive must be powerful enough to make the operator change its behavior in line with the PTA's objectives, and the PTA must also make sure the operator has the proper measures to affect the incentive's target. Similarly, the PTA needs to be aware of what control it gives away, what implication this has for its remaining possibilities to control the public transport system, and what potential adverse effects can arise following the incentive. The PTA must also make sure it is credible when it comes to enforcing the incentive. For that, proper monitoring is important. Ideally, the PTA should also evaluate the incentives it introduces, in order to infer whether they are effective or not. This is something that puts high requirements on data availability and adequate evaluation strategies. Examples of the latter includes introducing the incentive (randomly) at different points in time for different lines, and/or differentiating the price of the incentive across the same dimensions.

In addition to incentives, the PTA has other ways of ensuring quality in the contract. Ex-ante qualification criteria can help sort out poor operators, thus improving service quality, and reputational mechanisms, where the operator's performance during the contract term affects its chances of winning the next contract, could increase the operator's efforts to deliver good quality. One must also acknowledge that some tools of improving public transport lies outside the contract. Depending on the institutional settings, decisions on infrastructure, taxes, or environmental standard might lie outside the PTA's and operator's domain, thus making it necessary to collaborate with other parties than just the operator.

Introduction

Transportation improvements reduce the monetary or time costs of transportation. Improvements arise from technological advances in transport technology or from the expansion of transport infrastructure capacity; or come about because transport congestion is reduced, or from the pricing of transportation such as congestion pricing, gasoline taxation, parking taxes, or public transportation fares. There can also be improvements in the reliability of travel times, in the rates of traffic accidents or in the level of pollution and noise associated with transportation. In this article we will focus solely on how improvements in the monetary cost and time of travel affect property values.

The transport and property values connection has drawn the attention not only of urban economists, but also of urban planners, real estate professionals, and transportation planners and engineers. There are several reasons why it is useful to know how and how much property prices change because of transport improvements:

1. Aggregate property values are an important tax base, so changes in values affect the fiscal health of urban or suburban communities. For example, in the United States, property taxes are most often used to finance public schools.
2. Increases in property values can be potentially captured by special property tax levies, becoming revenues that can defray the cost of making the transport improvements that caused the property values to increase in the first place.
3. Predictions of changes in property values can indicate profitable investments in real estate markets surrounding a transportation project.
4. Changes in property prices are a part of the nonuser benefits of transport improvements and thus they are an important component of a cost-benefit analysis of a transportation project or of transport policy.

Of the above, Reason 4 is the most important to economists and deserves more comment here. It is often assumed that increases in property prices caused by a public transport investment equal the full benefits of the investment, but—as we shall see—this holds only when the utility levels of the consumers are not altered by the transport investment. More generally, we will see that a transport improvement can cause property prices to rise, to remain unchanged, or to fall. When prices rise (fall), consumers of property lose (benefit) while property owners benefit (lose). The cost-benefit analysis of transport improvements need to take into account the consumer surplus change experienced by households, the change in profits experienced by firms and the change in property prices accruing to property owners.

Noneconomists have often misconstrued the effect of transportation on property prices. For example, Melvin Webber, a Berkeley urban planning professor ruminating about the effect of the newly established BART (Bay Area Rapid Transit) system on real estate values, made a bold claim in 1976:

“ . . . land economists agree that rising values in one location will be about equally matched by declines elsewhere, rather as levels in an air mattress rise and fall as one section or another is squeezed or released. Unless the whole metropolitan economy has been caused to expand, the total of land values will remain essentially constant.”

(Webber, 1976)

Economic theory finds no reason for Webber’s “air mattress theory” and the empirical evidence does not support it. Land economists do not agree now nor did they agree back in 1976 or at any time that changes in aggregate property values caused by transport improvements are essentially zero unless the urban economy expands. Fifteen years before Webber’s conjecture, Mohring (1961) had proposed a simple but economically sound model of the real estate market’s connection with transportation. In

Mohring's model, a drop in transportation costs unambiguously increases or decreases aggregate urban property values, as we shall see later in this article, depending on whether the urban economy is open or closed in population. Extensions of Mohring's model since its publication have greatly advanced our understanding of the relationship between transportation improvements and property values and the relationship is much more complex than that imagined by Webber.

Transport improvements cause economic activity to shift among different locations altering the demands for floor space and land, causing new equilibrium prices for property. To understand the causal relationships, we will consider several theoretical treatments. In the first, we will see how improvements affect competitive firms located at different distances from an export hub, for example a harbor, to which they must ship their output. We will then consider how consumer-workers located at different distances from their jobs are affected in a residential land market. Results differ depending on whether the urban economy is closed or open to population movements. Next, we will review what the literature on the monocentric urban model of urban economics, in which all jobs are located at a single center, tells us about the transport and property prices relationship. Within the framework of the monocentric city, we also consider how road traffic congestion and its pricing affect property prices; the relative degree to which prices of floor spaces and of land are affected by transport improvements; and the effect of building durability on how property prices are affected. In the final section of this article, we consider the empirical evidence that has accumulated since the 1930s, distinguishing among three strands of such studies: before and after observations of the effects of specific transport projects; hedonic multivariate regression studies of how accessibility improvements are valued in real estate markets; and equilibrium models of the real estate markets in which the demand for and supply of real estate are separately identified.

Firms Located Relative to an Export Hub

Consider a firm that ships its output to the world market, by transporting it a distance x miles from the firm's production location to the harbor. Suppose that the firm produces Q tons of output and that the cost of transporting the output is t per each ton-mile. If the world price of the output at the harbor is p per ton, then the net (or effective) price per ton is $p - tx$. Suppose that the firm's production function is $Q = F(N, L)$ and constant returns to scale where the inputs are N units of labor and L units of land. The wage rate is w , and the land rent is R . Labor is assumed to be perfectly elastically supplied to any location. Hence, the wage rate is invariant by location. Suppose that the firm is operating in a competitive market, thus taking all prices and the transport cost as given. The firm maximizes profit with respect to the two input quantities:

$$\text{Max}_{N,L} \Pi = (p - tx)F(N, L) - wN - RL. \quad (1a)$$

Because of constant returns, the aforementioned can be normalized to a unit of land and maximized with respect to labor input per unit of land, or labor density $n \equiv (N/L)$:

$$\text{Max}_n \Pi = (p - tx)F(n, 1) - wn - R. \quad (1b)$$

The first order condition says that the labor density at x miles from the center is such that the value of the marginal product of labor employed at that location equals the wage rate:

$$(p - tx)F_n - w = 0. \quad (1c)$$

This is illustrated in Fig. 1.

By differentiating this with respect to t and n we get:

$$\frac{dn}{dt} = \frac{F_n x}{(p - tx)F_{nn}} < 0. \quad (1d)$$

Figure 1 In a market of competitive producers, shipping outputs to a transport hub causes labor density to fall with distance from the hub.

The sign follows from diminishing marginal product, $F_{nn} < 0$. Eq. (1d) is the proof that when the unit cost of transportation improves (t decreases) then the demand for labor increases at each location. The next step is to see what happens to the land rent at location x . Competitive firms make zero profit in the long run. Therefore, we can write from Eq. (1b) that

$$R = (p - tx)F(n, 1) - wn. \quad (2a)$$

Maximizing R is equivalent to maximizing profit. The Envelope Theorem applies (because Eq. (2a) is maximized with respect to n , we can get Eq. (2b) by differentiating Eq. (2a) with respect only to the direct effect of t on R through tx , ignoring the indirect effect through n), and it is easy to see that the rent increases at each distance from the harbor as the cost of transport per mile decreases:

$$\frac{dR}{dt} = -F(n, 1)x < 0. \quad (2b)$$

Result 1: In a market of competitive firms, if the per-mile cost of transporting output to the market is reduced, then the labor density, the firm's output and the land rent increase at each location where firms are operating.

Residential Location in an Economy Open to Population

We consider an economy's residential area consisting of many locations. The economy is open to population which means that consumers can move in and out of the economy at zero cost in response to transportation improvements. If the improvements raise (lower) the level of utility within the economy, new consumers will move in (out) until the level of utility falls back to the level prevailing outside the open economy.

Consider a consumer within the economy who has income Y and chooses residence location i . Suppose that the location i entails travel from that location with total monetary cost C_i and total travel time T_i . The travel could be commuting from the residence location to the consumer's workplace (wherever that might be) or it can include a fixed bundle of work and nonwork trips from the residence location to meet the consumer's needs.

Let the utility function of the consumer be $U(X_i, H_i, D - T_i)$, where X_i is the quantity of a numeraire composite good that is an aggregate of all goods other than housing, and H_i the quantity of housing floor space that the consumer will demand if he chooses residence location i . $D - T_i$ is the leisure the consumer enjoys after the time spent on travel is deducted from D , the total time available for leisure and travel. Assume as is reasonable, that all three goods—housing, leisure, and the composite good—are normal goods. The consumer takes as given his income Y and the travel time and monetary costs of transportation C_i and T_i .

The consumer maximizes utility with respect to X_i and H_i subject to the budget constraint $X_i + P_i H_i = Y - C_i$, where P_i is the unit market price of housing floor space in i . Travel time, T_i , enters the utility as a bad (imparting disutility) because it decreases leisure. The indirect (or maximized) utility of the consumer is:

$$V(Y - C_i, P_i, D - T_i). \quad (3)$$

From Eq. (3), the marginal rate of substitution (MRS) between monetary travel cost and travel time can be derived by totally differentiating Eq. (3) with respect to T_i and C_i , while keeping the level of utility constant:

$$\frac{\partial V}{\partial C_i} dC_i + \frac{\partial V}{\partial T_i} dT_i = 0 \Rightarrow MRS(C_i, T_i) = \frac{dC_i}{dT_i} = -\frac{\partial V / \partial T_i}{\partial V / \partial C_i} < 0. \quad (4)$$

This MRS is often called the value of time (VOT) of the consumer. It tells us how much more the consumer would be willing to pay in monetary cost for a marginal reduction in travel time. The importance of Eq. (4) becomes apparent when we consider that consumers of different types, more precisely of different incomes, benefit differentially from the same transportation improvement. Higher income consumers have a high marginal disutility of travel time (high marginal utility of leisure) and a low marginal utility of disposable income. Hence, such consumers have a higher VOT than do lower income consumers. When the monetary cost of transportation does not normally vary much with a consumer's income while the MRS does vary more, any travel time improvement will generally be more valuable to the higher income consumers.

A second important property is the demands for housing floor space and the composite good, obtained by applying Roy's identity to Eq. (3) to get the former and then using the budget constraint to get the second:

$$H_i^* = -\frac{\partial V / \partial P_i}{\partial V / \partial (Y - C_i)} = H(Y - C_i, P_i, D - T_i). \quad (5a)$$

$$X_i^* = Y - C_i - P_i H_i^* \quad (5b)$$

Suppose that a transportation improvement decreases the monetary cost or the travel time or both. *Keeping income and the price of housing unchanged*, how will such a change affect the quantity of housing demanded? Because the monetary cost of transportation decreases from C_i to C_i' , disposable income increases and this works to increase the demand for the normal good H_i . But there is another effect because the transportation improvement increases leisure too. H_i^* will increase if housing and leisure are sufficiently complementary in consumption. H_i^* will decrease if composite good and leisure are sufficiently complementary in consumption.

More precisely, if the utility function is $U = u(D - T)v(X, H)$ and, hence, homothetic in X and H regardless of the level of leisure, then reducing travel time, T , does not change the quantity of X and H demanded by the consumer, but it does increase leisure and the level of utility. Instead, consider that $U = U[u(D - T, X), H]$ or $U = U[u(D - T, H), X]$. In the former leisure and consumption can be made complementary by choice of the subutility function $u(\bullet)$, and in the latter leisure and housing can be similarly made complementary.

Now, suppose that initially the population of consumers in the open economy choosing residence location i is N_i . Assume that, in the short run, N_i remains constant in response to the transport improvement. Then, the aggregate short run demand for housing at residence location i is $N_i H_i^*$ and will increase when H_i^* increases. Keeping the housing supply function unchanged but assuming that it is not perfectly elastic, the equilibrium price of housing will increase when leisure and housing are complementary enough in consumption. In the case where housing and leisure are strong enough substitutes, the aggregate demand for housing at residence location i can decrease and so will the equilibrium price of housing.

The next step is to allow mobility between different locations to gain insight about long run changes in the open economy and the effect on property prices. Assuming that all consumers have the same utility function and the same income and can change location at zero cost, what will be the long run equilibrium outcome? Consumers will relocate to those places where the transport improvement increased utility and this process will continue until the utility level is the same everywhere and there is no longer any gains from further relocations. Consider two locations i and j . Suppose that the transport improvement occurs only in location i . Thus before the improvement, we have the equilibrium condition that:

$$V(Y - C_j, P_j, D - T_j) = V(Y - C_i, P_i, D - T_i). \quad (6a)$$

After the improvement, we have that $C_i' < C_i$ and that $T_i' < T_i$, and therefore:

$$V(Y - C_j, P_j, D - T_j) < V(Y - C_i', P_i, D - T_i'). \quad (6b)$$

To bring the utility in location i back to equilibrium, the housing price must increase in the long run, so we have that $P_i' > P_i$:

$$V(Y - C_j, P_j, D - T_j) = V(Y - C_i', P_i', D - T_i'). \quad (6c)$$

From Eq. (6c), keeping the utility level constant before and after the transport improvement, we see that:

$$\frac{dP_i}{dT_i} = \frac{\partial V / \partial (D - T_i)}{\partial V / \partial P_i} < 0; \quad \frac{dP_i}{dC_i} = \frac{\partial V / \partial (Y - C_i)}{\partial V / \partial P_i} < 0. \quad (7)$$

Result 2: Either a monetary cost improvement or a travel time improvement in the transportation associated with a location unambiguously increases the housing price of that location when the level of utility is fixed.

Result 2 is illustrated in **Fig. 2**. The indifference curve bb' lies below the indifference curve aa' . Both indifference curves correspond to the same utility level, because bb' includes the effect of a lowered travel time, hence involves consumption-housing bundles with more leisure. The vertical intercept of the budget line is the disposable income and the lowered monetary transport raises disposable income, while the absolute value of the slope of the budget line is the housing price. We can see from the **Fig. 2** that the tangency between the budget line and the indifference curve bb' must occur at a higher housing price and a lower housing quantity demanded. Hence, a transport improvement which lowers travel time (increasing leisure) and/or lowers monetary travel cost, raises the price of housing when the level of utility is fixed, and reduces the demand for housing. A fixed utility level is assumed to be the condition in a city open to the in- and out-migration of population.

Figure 2 A transport monetary cost or travel time reduction at a location, raises the price of housing and reduces the quantity of housing demanded when the level of utility is fixed.

A second equilibrium condition makes it possible to determine the population that wants to locate at i . This is the condition that the housing market at location i clears:

$$N_i H_i^* - S_i(P_i) = 0. \quad (8)$$

$N_i H_i^*$ is the aggregate demand for housing floor space, and $S_i(P_i)$ is the upward sloping housing supply. By Result 2, the transportation improvement causes H_i^* to decrease and P_i to increase, hence N_i also increases. Hence, $\frac{dN_i}{dT_i} < 0$, and similarly $\frac{dN_i}{dC_i} < 0$.

Result 3: A lowered monetary cost or travel time associated with location i unambiguously increases the consumer population residing at location i when the level of utility is fixed.

Residential Location in an Economy Closed in Population

In an economy closed in population, the level of utility will be endogenously determined. Suppose that $N = \sum_{i=1, \dots, n} N_i$ is the total population initially distributed among n residence locations. After transportation is improved, this population will be redistributed so that $N = \sum_{i=1, \dots, n} N_i'$, where N_i' is population at i after. Intuitively, we expect that locations where transportation is improved relatively a lot, will attract population from the locations where transportation is improved relatively less or not improved at all. To obtain precise results, consider just two locations and assume that only travel time in location 2 is reduced. The equilibrium conditions are:

$$V(Y - C_1, P_1, D - T_1) = V(Y - C_2, P_2, D - T_2), \quad (9a)$$

$$N_1 H_1^* - S_1(P_1) = 0, \quad (9b)$$

$$(N - N_1) H_2^* - S_2(P_2) = 0. \quad (9c)$$

The three unknowns to be solved are P_1 , P_2 , and N_1 . By comparative static analysis of Eqs. (9a)–(9c), and assuming a utility function that is homothetic in housing and the composite good so that changes in leisure do not affect housing demands, it is shown that $\frac{dP_2}{dT_2} < 0$, $\frac{dP_1}{dT_2} > 0$, $\frac{dN_1}{dT_2} > 0$. The details of the comparative statics analysis are left as an exercise for the reader. The result generalizes to the case of an improvement in the monetary cost of transportation at location i .

Result 4: In an economy with two locations and closed in total population, a transport improvement associated with one location causes the housing price at that location to rise and the housing price at the other location to fall, while the population will be reallocated in the margin from the other location to the location where transportation improved.

Fig. 3 illustrates Result 4. For simplicity, the demand and supply functions in **Fig. 3** are drawn as linear. The demand function for floor space shifts to the right in location 2 while it shifts to the left in location 1, as the transport improvement in location 2 induces consumers in the margin to relocate from 1 to 2. How much the unit price of floor space rises in location 2 and how much it falls in location 1 is determined by the price elasticities of the two housing demand and housing supply functions.

The aggregate value of floor space at equilibrium is $\sum_{i=1,2} P_i N_i H_i(P_i) = \sum_{i=1,2} P_i S_i(P_i)$. The change in the aggregate housing price can be positive or negative, which again debunks Webber's air mattress theory. Additional information in **Fig. 3** is the aggregate land value (and its change) at each location. As is well known, aggregate land value is the producer surplus accruing to the landowner, and that is measured by the triangular area below the equilibrium price line and above the supply line. The Figure makes it clear that aggregate land value falls in location 1 and rises in location 2, while the combined aggregate again depends on the demand and supply elasticities. To sum up, what happens to the aggregate value of floor space also depends on whether the utility of residents remains unchanged. This holds, as we saw, when the urban economy is open.

As stated in the Introduction, the assumption of openness or closedness plays an important role in the cost-benefit analysis of transportation projects. Whether an economy should be modeled as open or closed is itself a nontrivial issue. Consider, for example, that transport improvements occur in some cities within a national economy. It would be appropriate to consider that in the long run population from other cities would migrate to the cities where the improvements occurred. Cities, therefore, should be modeled as open in population. We might observe higher property prices in the cities where improvements occurred while property prices in the other cities could be lowered if the national economy as a whole is closed in population.

Figure 3 A transport improvement at location 2 raises the price of housing at location 2, lowering it at location 1 when the total population of the two locations is fixed but mobile between the two locations.

Transport Improvement in the Monocentric City

A powerful model used in urban economics is the monocentric model of urban land use equilibrium. The model assumes that all workers who are also consumers work at a central point, dubbed the central business district (CBD), and that the city's residential area is confined to the area of a circle around this central point. As a simplification, imagine that the roads leading to the CBD are densely distributed, so that any worker can travel to the CBD on a radius. It is assumed that the land market operates as an auction so that every location in the city goes to the consumer-worker bidding the highest rent for that location. Whether landlords own small pieces of land or one landlord owns all of the land makes no difference, because to maximize profits under perfect information, landowners must rent each parcel of land at the highest possible rent, hence to the highest bidder. The radius of the residential area is determined by arbitrage in the land market, so that at equilibrium at the urban edge the residential bid rent equals the exogenous agricultural rent.

A very simple version of the monocentric city model, mentioned earlier in this article, was proposed by [Mohring \(1961\)](#). In this model, a consumer rents a unit amount of land regardless of residential location x miles from the CBD and transport costs are linear in distance and t per mile. Mohring's simplification ignores the fact that where rents on land are lower, consumer-workers may rent more land causing the lot size per worker to increase with distance from the CBD. Yet, Mohring's model served as a very useful first step for understanding the relationship between land values and commuting costs in a monocentric city. We will now explain how the model works when the city is open or closed in population.

Assuming that all consumers working in the CBD have the same income Y , the budget constraint can be used to see that the consumption of all other goods, treated as a composite is $X(x) = Y - R(x) - tx$, where $R(x)$ is the rent at distance x and tx the cost of commuting to the CBD. For the consumers to be in equilibrium (not to want to relocate within the city), $X(x)$ —which is also a measure of the consumer's utility because lot size, the other good, is fixed—must be the same at each x . This in turn, requires that $R(x) + tx$ be the same at each x . Hence, $R(x) = R(0) - tx$. At the border of the city $x = \bar{x}$, and the equilibrium urban rent there is equal to the agricultural rent on land, r , by the no arbitrage condition: $R(\bar{x}) = r$ and $\bar{x} = [R(0) - r]/t$. In a circular city, the rent falling linearly in all radial directions at the same rate per mile, traces the surface of a cone the base of which is the surface area of the city. The volume of this cone is the aggregate rent, while the remaining volume of the cylinder with the same base within which the cone sits is the aggregate transportation cost. When t falls, both aggregate rent and aggregate transport costs increase and the open city expands in radius and area accommodating additional population, but aggregate rents always remain at one half of aggregate transport costs. If the city is closed in population, then the fixed lot size assumption implies that the city's radius and area cannot change. The arbitrage condition at the city border still requires that $R(\bar{x}) = r$ and so $R(0)$ must fall causing a higher utility level throughout the city. In this case, aggregate transport costs and aggregate rents fall, but the two-to-one relationship is still preserved at a higher level of utility.

In Mohring's simple model, when the city is open, Webber's air mattress conjecture never holds since a transport improvement always increases aggregate rents as well as aggregate transport costs. And when the city is closed, the air mattress conjecture again never holds as a transport improvement decreases aggregate rents. [Arnott and Stiglitz \(1981\)](#) showed that the two-to-one ratio is robust under various generalizations of Mohring's simple monocentric model.

The monocentric model of Mohring was extended and became much more realistic by the initial efforts of [Alonso \(1964\)](#), [Mills \(1967\)](#), [Muth \(1969\)](#), and [Strotz \(1965\)](#) all of which were available to Melvin Webber. Here, let us consider our own version of the monocentric model. Assume that all consumer-workers have identical preferences $U(X, q, D - T)$ where, as before, X is the quantity of a numeraire composite good, q is the quantity of land the consumer rents (housing is ignored here) and T is the travel time from the consumer's residence location to the CBD. As before, D is total time available and $D - T$ is leisure. The consumers all have income, Y , and incur monetary transportation cost given by the function $C(x)$. The consumers achieve the same utility level, u , at equilibrium no matter where in the city they locate. From the budget constraint, the highest rent that can be bid for a unit piece of land located at distance x from the CBD is:

$$R(x) = \frac{Y - C(x) - X[u, q(x), D - T(x)]}{q(x)}, \quad (10a)$$

where $X[u, q(x), D - T(x)]$ is the indifference surface between the composite good, the lot size and leisure. The landlord who owns land at location x is a utility taker and will maximize the rent he can charge with respect to $q(x)$. Finding the optimal value $q^*(x)$ tells the landlord how much land each of his parcels-for-rent should contain. An important issue in the model is the rent gradient, that is, the rate at which the rent changes with distance from the CBD. This can be found by applying the Envelope Theorem to Eq. (10a) (The Envelope Theorem in this case means that since the landlord maximized Eq. (10a) with respect to $q(x)$, the derivative of $R(x)$ can be found by differentiating Eq. (10a) with respect to the direct effects of x only, that is the effects through $C(x)$ and $T(x)$). Doing so gives:

$$\frac{dR(x)}{dx} = -\frac{1}{q^*(x)} \left[\frac{dC(x)}{dx} - \frac{\partial X}{\partial (D - T(x))} \frac{dT(x)}{dx} \right] < 0, \quad (10b)$$

where $\frac{dC(x)}{dx} > 0$ is the rate at which transport cost at location x increases with distance, and $q^*(x)$ is the optimal lot size at distance x . $\frac{\partial X}{\partial (D - T(x))} < 0$ is how much composite good the consumer would want to receive to be compensated for a marginal decrease in leisure keeping constant the lot size and the level of utility. Hence, this term is the consumer's "value of time" or VOT. If leisure is not in the utility function, then $VOT = 0$ and Eq. (10b) reduces to $\frac{dR(x)}{dx} = -\frac{1}{q^*(x)} \frac{dC(x)}{dx} < 0$, also known as Muth's condition ([Muth, 1969](#)). Suppose that the monetary commuting cost is linear with distance with slope t , then Muth's condition becomes $\frac{dR(x)}{dx} = -\frac{t}{q^*(x)} < 0$. The

presence of leisure in the utility function causes the rent gradient to increase, steepening the rent-distance function. As the consumer's income increases, there are actually two countervailing effects. On the one hand the *VOT* should increase because richer consumers value their travel times more highly, causing the term in the brackets in Eq. (10b) to increase; while, on the other hand, the demand for lot size increases with income causing $q^*(x)$ to increase. While the *VOT* effect steepens the rent-distance function, the lot size effect flattens it as income increases.

Wheaton (1977) showed by empirical analysis for the San Francisco Bay area using 1960 Census data that the income elasticity of the demand for lot size is bigger than the income elasticity of *VOT*. Hence, the rent-distance function gets flatter with income which supports the more peripheral location of the rich as compared to the central location of the poor in US cities. However, adequately explaining the full flattening of the rent-distance function with income requires recognizing that not only does the demand for lot size increase with income but so do also other important demands such as the demand for public services, safe neighborhoods, open spaces, and school quality. Because these attributes increase with distance from the CBD due to historical trends in the outward development of cities, the slope of the rent-distance function of Americans flattens out robustly with income.

How does the equilibrium rent-distance profile of the monocentric city respond to a lowering of the per mile monetary and/or time cost of commuting to the CBD? This question was examined in Wheaton (1974). The result, illuminated by our Fig. 2, applies to an open monocentric city: as the unit cost of commuting decreases, rent increases at each distance from the CBD because the utility level is fixed. In a city closed in population, the result is illuminated by our Fig. 3. Because the monetary and/or time cost of commuting cost decreases, a far-from-the-CBD location affords higher disposable income and/or more leisure than before. As a result, this increases the demand for peripheral locations at the expense of central ones. Moving out to the periphery where land is cheaper, consumers can rent larger lots. As a result, rents in the central locations fall while rents rise in the peripheral locations. This basic result is at the heart of why housing decentralized after the car became widely utilized and also explains why the property tax base of central cities decreased.

The monocentric model as exposit by Strotz (1965) and Alonso (1964) lacked housing as did Mohring's. Housing services were proxied by the lot-size variable, also true in our version earlier. This deficiency was corrected by Muth (1969) who showed that, at equilibrium, the structural density of buildings (housing in particular) will decrease with distance from the CBD. An important result is that the rent of housing floor space declines much more gently than does the rent on land. This property is intuitive if we recall that the amount of land at every distance from the CBD is perfectly inelastically supplied since new land cannot be created at any location, while the supply of floor space at any distance can be increased by building taller buildings. Building developers constructing closer to the CBD build taller buildings because they are confronted with higher land prices there, whereas it is plausible that the prices of structural inputs (concrete, bricks, glass, steel) are perfectly elastically supplied to any location in the city. The substitution of capital for land in the construction of floor space causes the structural density of buildings to decrease with distance from the CBD.

To illustrate this result, consider that identical consumers all have income Y , and a utility function defined over two goods: housing floor space H and all other goods X , ignoring leisure in this case. Suppose also that transport cost is linear with distance x from the CBD with per-mile transport cost, a constant t . Assume also that the utility function is Cobb–Douglas: $U = X^\alpha H^{1-\alpha}$, $0 < \alpha < 1$. Floor space is produced by competitive developers operating under constant returns to scale and combining land inputs, L , and capital inputs, K . Let this be a Cobb–Douglas production function: $H = K^a L^{1-a}$, $0 < a < 1$. Capital is perfectly elastically supplied to any location within the monocentric city. It is easy to show that under these assumptions, the equilibrium rent on floor space, $P(x)$, and the equilibrium rent on land, $R(x)$, decline with distance according to power laws as follows:

$$P(x) = C_1(Y - tx)^{\frac{1}{1-\alpha}} \quad \text{and} \quad R(x) = C_2(Y - tx)^{\frac{1}{(1-\alpha)(1-a)}}. \quad (11)$$

C_1, C_2 are constants. Plausible values are $\alpha = 0.75$ for the share of disposable income allocated to all goods other than housing, and $a = 0.9$ for the cost-share of capital in building development. Hence, the exponents in Eq. (11) are $\frac{1}{1-\alpha} = 4$ and $\frac{1}{(1-\alpha)(1-a)} = 40$. Consider now the elasticity of the two prices with respect to the unit transportation cost t . As t falls denoting a transport improvement, both prices increase, but the price on land increases 10 times more than does the price on floor space.

A final comment on the monocentric model is that, in all its versions discussed above, the city is assumed to be malleable in structural capital. Determined from scratch and, ignoring all adjustment costs, it transforms instantly into a new equilibrium when the economy changes. This condition does not hold in reality since buildings are durable and adjust slowly to changes in economic conditions. Consider, for example, the case of infinitely durable buildings and the city expanding from the CBD outwards over time, growing like a tree trunk, where a ring of new land development is added to the tree trunk's outer edge every time period. This case was examined by Anas (1978).

The basic insight of Anas (1978) can be derived from Eq. (10a) with the caveat that since buildings are inherited from the past, the lot size $q(x)$ which proxies housing will be taken as an exogenous function determined by history. Only at the current edge—the most recent ring in the tree trunk—of the growing city is $q(x)$ determined by current economic conditions. It follows that in this case, the modified Muth's condition will differ from Eq. (10b), and the Envelope theorem can no longer be used. The condition now becomes (recalling our assumption that leisure does not enter the utility function):

$$R'(x) = -\frac{C'(x)}{q(x)} - \frac{R(x) - |MRS(X, q(x))|}{q(x)} q'(x), \quad (12)$$

where $MRS(X, q) < 0$ is the marginal rate of substitution between lot size and the composite good. Only at the edge of the city, where development happens currently, does rent equal the *MRS*. In that case the second term vanishes and Muth's condition holds locally

at the edge of the city. For all other locations between the CBD and the edge of the city, the rent gradient deviates from Muth's condition in general. Consider, for example, the case where a city's income and utility have been growing over time and in such a way that $q'(x) > 0$ over all locations, that is in each period houses with larger lot sizes have been built while, once built, all older lot sizes remained unmarketable. Under such a growth profile, it is possible that $R(x) < |MRS[X, q(x)]|$. This circumstance can make the second term in Eq. (12) positive and dominating over the first term, thus causing the rent on land to be rising with distance from the CBD until at some intermediate distance it begins to decrease again. How does a transport improvement affect the rent gradient under these conditions? On the one hand, the improvement changes the gradient by making the first term in Eq. (12) more negative. On the other hand, the transport improvements occurring over time can increase $q'(x)$ too, and this reinforces the tendency for a rent that increases with distance.

Congestion and Congestion Pricing

The effect of traffic congestion on property prices is complex. In the literature, this effect has been examined mostly within the narrow setting of a monocentric city. [Strotz \(1965\)](#) was the first to model congestion in the monocentric city and the theme was picked up again in the 1970s by many authors. The common approximation is that all traffic arrives at the CBD at the same point in time each morning. This means that the commuter residing at the edge of the city departs first and commuters residing at closer-in distances join the traffic stream when it passes their location. This accumulation of traffic increases the cost of travel per mile nonlinearly with distance from the CBD, the closer the mile being to the CBD, the higher the cost of travelling it. Assuming that the presence of congestion does not disturb the location of the jobs in the CBD, residents can economize in the presence of congestion only by moving their residence locations closer to the CBD, and thus reducing the total effect of congestion on them. Rents on land and floor space near the CBD increase and so do structural and population densities closer to the CBD, while the city gets more compact (shorter radius). Pricing congestion, again assuming no changes in job locations, exacerbates this effect. There is only one margin along which commuters can blunt the effect of the congestion tolls on them. They can do so only by moving closer to the CBD which raises rents near the CBD even more, making the city even more compact than the initially unpriced congestion did.

Of course, the effect of congestion on job location is too important to be ignored. [Anas and Kim \(1996\)](#) showed that congestion and congestion pricing can cause firms and the jobs they offer to move out of the CBD and to agglomerate in new subcenters, causing the monocentric city to become polycentric. The process of subcenter formation in a city closed in population raises property prices at the subcenter locations, lowering property prices at the CBD. [Anas and Pines \(2013\)](#) showed that pricing congestion in each city of an economy with identical cities causes the number of cities to increase, each city becoming smaller and rents near the CBDs of the cities falling as new cities emerge to decongest the existing cities. This result underscores the limitation of the analysis of the solo monocentric model in which it is assumed that when congestion increases neither jobs nor residents can move to other cities. Because in the solo monocentric city, intercity mobility is assumed not to happen, density near the CBD increases and so do rents.

The Empirical Evidence

There have been three types of empirical studies that have documented that transport improvements affect property prices in cities.

Before and After Comparisons

The first type of study dates as far back as the 1930s and dealt with actual transport projects, looking to descriptively document changes in property values using before and after observations. Many of these studies tried to establish that there was a positive relationship between travel time and travel cost savings made possible by the projects and observed increases in property values. [Spengler \(1930\)](#) and [Davis \(1965\)](#) examined the effect of rapid transit projects on property values in New York and Northern Chicago, respectively. [Adkins \(1959\)](#) examined expressways in Dallas, Houston and San Antonio; [Lemly \(1959\)](#) along Atlanta's expressways; and [Golden \(1968\)](#) examined Chicago expressways. [Wootan and Haning \(1960\)](#) focused on interstate highways in Austin, Texas; and [Ashley \(1965\)](#) on interchange development along I-94. A suburban commuter railroad's effects on property values were evaluated by [Boyce et al. \(1972\)](#) who studied the Lindenwold-Camden-Philadelphia line.

Hedonic Regression Analysis

A second type of study became common in the 1970s and has continued until recent times. Authors relied on hedonic multivariate regression analyses to show positive effects of transport projects on property values while controlling for other effects. Among these are those by [Deweese \(1976\)](#) who studied the effects of subway stations on Bloor street in Toronto on property values and also of [Bajic \(1983\)](#) for Toronto. [Damm et al. \(1980\)](#) studied how the announced opening of the Washington DC METRO stations affected real estate prices near the station locations. [Voith \(1993\)](#) studied Philadelphia, [Gatzlaff and Smith \(1993\)](#) studied the Miami Metrorail, and [Hess and Almeida \(2007\)](#) studied the effects of the Buffalo light rail line on property values. Hess and Almeida also provided a thorough list of many other similar studies for various US cities that implemented new transit stations until relatively recent times. In the last decade a plethora of studies, too numerous to mention here, have implemented similar methods for Asian public transportation projects.

While studies mentioned here and many of the others found positive effects of transit stops on nearby real estate prices, in some cases the positive effects on housing prices are confounded by negative effects from the noise externalities and the commercial developments that arise as transit stations induce changes in the real estate market. Bowes and Ihlanfeldt (2001) attempted to disentangle some of these effects. They argued that while stations may raise the value of nearby properties by reducing commuting costs or by attracting retail activity to the neighborhood, countering these positive effects are the negative externalities emitted by stations and the access to neighborhoods that stations might provide to criminals. Both of these auxiliary effects which are endogenous to the transport improvement would negatively affect property prices, and more so closer to the stations.

A shortcoming of the hedonic approach is that it models real estate prices at equilibrium but cannot distinguish between the transportation project's influences on the demand for location and the supply of floor space available at that location. Suppose, for example, that the demand and the supply of floor space in a neighborhood near a transport improvement are given by the following two equations:

$$D = a + bP + cZ + dT + \varepsilon_1 \quad \text{and} \quad S = e + fP + \varepsilon_2, \quad (13a)$$

with the coefficient $b < 0$ and the coefficient $f > 0$. P is the unit price of floor space, Z are various neighborhood characteristics, and T is the travel time measure associated with the transport improvement with the coefficient $d < 0$: for example a lowering of travel time, T , increases the demand to locate in the neighborhood. Assume in this example that the Z are all exogenous so that no endogeneity bias arises. The error terms are ε_1 and ε_2 . It is assumed that the variables Z , T do not directly affect the supply side. At equilibrium, $D = S$ implies the following hedonic relationship that is to be estimated:

$$P = \underbrace{\frac{e-a}{b-f}}_{\equiv \alpha_0} - \underbrace{\frac{c}{b-f}}_{\equiv \alpha_X} Z - \underbrace{\frac{d}{b-f}}_{\equiv \alpha_T} T + \underbrace{\frac{1}{b-f}(\varepsilon_2 - \varepsilon_1)}_{\equiv \varepsilon} \quad (13b)$$

Note that $b - f < 0$. Eq. (13b) is always estimated as $P = \alpha_0 + \alpha_X Z + \alpha_T T + \varepsilon$. If $c > 0$, then $\alpha_X = -\frac{c}{b-f} > 0$, and since $d < 0$, then $\alpha_T = -\frac{d}{b-f} < 0$. While the regression captures the equilibrium effect of a $\Delta T < 0$ causing a $\Delta P > 0$, it cannot distinguish the direct demand effect of ΔT from the effect of ΔP on the supply increase. If the estimated coefficient α_T is large in absolute value, it is correctly concluded that a travel time reduction has a large effect on price, but nothing is learned about whether this large effect stems from the effect of travel time on demand or from the price inelasticity of the floor space supply function. If, for example, the supply of floor space is nearly perfectly elastic as it might be in a suburban area with plenty of land that is properly zoned and ripe for development, then the coefficient f would be large and positive resulting in the estimated α_T to obtain a very small negative value. That is, the true effect of the highway project on demand is obscured by the large supply elasticity.

Market Equilibrium Simulations

The third type of study is designed, in part, to overcome the shortcoming of the hedonic studies explained earlier. In this third type of study, microeconomic equilibrium models are used empirically to simulate the effect of projects on the real estate market. Anas (1982) and Anas and Duann (1985) presented the Chicago Area Transportation and Land Use Analysis System (CATLAS), a model which relied on empirically estimated probabilistic location choice and housing supply equations to estimate the response of the housing market to a new rail transit project planned for Chicago's Southwest Corridor. The CATLAS model was estimated using 1970 US Census data and other complementary data. 1980 Census data could not be used due to the timing of the study. So the planned project was modeled counterfactually both because it did not yet exist and because it was modeled under 1970 conditions.

A project similar to one of the alignments that was studied by the CATLAS model was actually built and opened for service about 8 years later on October 1, 1993, and is now known as the 11 miles long Orange Line which connects downtown Chicago with Midway airport. The CATLAS model divided the Southwest Corridor area into small square zones of $\frac{1}{2}$ mile edges around the proposed alternative transit alignments and into larger square zones of 1 mile edges in the suburbs. The entire Chicago MSA was covered by 1690 such zones of which 205 were located within the Southwest Corridor (137 within the City of Chicago and 68 in the suburbs). The model accounted for walking, feeder bus, and driving with and without parking ("kiss and ride" and "park and ride") as alternative methods for accessing the proposed transit stations. The model accounted for the residential location choices made by workers employed in the Chicago CBD as well as those employed in nonCBD workplaces. Nonwork trips could not be included in the model because data on such trips were not available.

The core of the CATLAS model is described by the following equation system that expresses the short run market equilibrium in the zones of the region:

$$\sum_{h=1,2} N_h \sum_{m=1,\dots,4} P_{him}(\mathbf{R}, \mathbf{T}, \mathbf{C}) = S_i \Phi_i(R_i); \quad i = 1, \dots, 1690. \quad (14)$$

In this equation, $h = 1$ denotes CBD commuters and $h = 2$ nonCBD commuters, where N_h is the given number of such consumers. $P_{him}(\mathbf{R}, \mathbf{T}, \mathbf{C})$ is a nested multinomial logit model of choice among residential zones i and the four modes of travel (car, bus, rail, and other) estimated by maximum likelihood. This choice probability depends on the rent, $\mathbf{R}$, travel time, $\mathbf{T}$, and monetary travel cost, $\mathbf{C}$, vectors of all the zone-mode combinations via a utility function that depends on various zone characteristics and zone and mode specific constants. S_i is the stock of existing housing units in zone i , and $\Phi_i(R_i)$ is the probability that a landlord will offer his housing

unit to the market than keep it vacant, estimated by maximum likelihood. Hence, $1 - \Phi_i(R_i)$ is the housing vacancy rate in zone i . $S_i\Phi_i(R_i)$ is the short run supply function of zone i .

The CATLAS model showed rent increases for the housing in the zones located near the planned stations and in some suburban zones that had good access to planned suburban stations with projected parking availability. The alternative proposed rail transit projects that were studied were found to cause commuters in the margin to shift residences from the suburbs to the central city zones and to the suburban zones that had good access to stations with parking. The alignments studied by the CATLAS model extended beyond Midway airport, but this part of the alignment was not actually constructed later. Thus rents in the central city zones increased while those in some of the suburban zones decreased, but overall aggregate rents in the corridor increased from 1.48% to 1.80% for the three alternative proposed rail alignments (from 2.14% to 2.92% in the central city part of the corridor; and from 0.70% to 0.73% in the suburban part). The highest rent increase was \$247 and the average was \$25 per housing unit per year about a 10% increase near the proposed transit line under 1970 conditions and in 1970 dollars. Estimated increases in the consumer surplus varied from 2.3% to 2.9%. The aggregate rent increase within the corridor varied from \$6.4 to \$8.2 million per year for the three alternative alignments, and discounting this with an appropriate interest rate, it was found that the aggregate rent increases, if they could be recovered by an incremental special assessment tax within the Southwest Corridor, would potentially defray from 25.8% to 36.1% of the capital costs of implementing the alternative projects studied by the model.

After the opening of the Southwest Corridor's Orange line, McDonald and Osuji (1995) and McMillen and McDonald (2004), examined how house prices actually changed in response to the anticipation of the opening and after the start of the operation of the line in 1993. The first paper pools house price data from 79 city blocks near the Orange line for which prices are observed for 1980 and 1990 before the line had opened, but its opening was announced and broadly assumed by market agents in 1990. The second study used repeat sales analysis of 4056 single family houses that sold more than once between 1983 and 1999, that is from 10 years before to 6 years after the line's opening. Both studies showed that prices began increasing prior to the opening of the line in anticipation of the future travel time savings. As for the magnitude of price increases, the results are in close agreement with those of the CATLAS model's equilibrium predictions prior to the construction of the Orange line, despite the different data sources and modeling assumptions. The CATLAS model using 1970 data predicted a 10% increase in housing prices within ½ mile of stations while McDonald and Osuji (1995) measured a 17% increase, and McMillen and McDonald (2004) using the repeat sales approach measured a nearly 7% increase for the same compared to the 10% prediction of the CATLAS equilibrium model, a prediction made 8 years prior to the project's opening and with a model calibrated with outdated data, that was nevertheless the best available at the time.

Introduction

This article provides an overview of existing empirical evidence on the effect of transport improvements on firm-level private output and productivity. The discussion focuses on the more recent research adopting a microeconomic production function framework, while the previous article considered the older and more conventional approach based on national and regional macroeconomic analyses. These earlier estimates of the output elasticity of transport investment obtained from more aggregate-level studies tended to suggest strong economic growth benefits and were often used by politicians to justify government funding for new and improved transport infrastructure. More recent evidence shows that many of these studies identified spurious relationships by failing to address the main identification challenges in this literature, in particular, issues of firm self-selection and reverse causality between transport investment and economic performance.

Firm- and plant-level studies are relatively recent in this literature, partly due to data availability reasons. One of the main advantages of the microeconomic approach based on longitudinal firm data is that it offers the opportunity to better examine some of the mechanisms underlying performance differentials in the spatial economy. Importantly, this approach can distinguish between the effects from within-plant or firm productivity growth, firm selection effects whereby more productive firms sort into locations with better transport accessibility, and displacement effects whereby new entrants with higher productivity replace older poor performing firms.

It is not the intention of this article to provide an exhaustive discussion of the ways in which transport infrastructure investment impacts on productivity and economic growth. There are a number of valuable surveys on the economic effects of transport infrastructure, whose references are provided as further reading at the end of this article. Transport infrastructure improvements lower transport costs and improve accessibility to input (i.e., suppliers, labor, etc.) and output markets, producing several impacts on the economy. These effects include, among other factors, the expansion and integration of wider markets, leading to productivity gains from improved labor supply and specialization; higher efficiency through scale economies and economic restructuring due to firm entry and exit resulting from stronger competition; and productivity effects from spatial agglomeration economies.

The impacts of transport improvements on the economy can be directly captured by the travel time savings, or generalized travel cost savings, accruing to transport users for work and nonwork purposes and indirectly through transfer to other users such as consumers and house and landowners. However, some of the economic benefits resulting from transport infrastructure investments are thought to be additional to transport user benefits and thus are not captured in conventional cost–benefit analysis. The most prominent example of wider economic benefits refers to the productivity gains from transport-induced agglomeration externalities. By changing the way people and firms have access to economic activity, transport affects the realization of agglomeration externalities and hence the productivity effects derived from it. In contrast, however, productivity gains resulting from industry reorganization should not be counted as additional because they are captured as a transfer in transport demand and thus the conventional appraisal of transport investment projects.

In brief, this article is structured as follows. Following the outline of the main effects of transport infrastructure investment on firms' output and productivity provided in this section, Section "Empirical Evidence From Microeconomic Firm-Level Studies" discusses the current state of the art of the empirical literature in relation to the approaches used to capture changes in economic access resulting from transport improvements (Section "Measuring the Effect of Transport Improvements: From Distance to Generalized Travel Cost"), the main identification challenges and strategies adopted (Section "Identification Issues and

Figure 1 Histogram of transport elasticity estimates from firm microeconomic studies using market potential type measures (top panel) and distance measures (bottom panel).

Strategies”), the extent of industrial heterogeneity (Section “Industrial Heterogeneity”), and the scope for and nature of spatial effects (Section “Spatial Heterogeneity”). Section “Conclusions” provided some tentative conclusions and emphasizes some of the main challenges guiding future research.

Empirical Evidence From Microeconomic Firm-Level Studies

This section provides an overview of the current state of knowledge from empirical microeconomic studies using firm- or plant-level data on the nearly 450 elasticity estimates obtained from the 13 studies listed in Appendix A and summarized in Appendix B according to whether they use a transport measure based on market potential type accessibility indicators (12 studies, 314 estimates) or distance to the nearest access point to the transport network (2 studies, 140 estimates). Fig. 1 shows the histogram of the elasticity estimates separately for the two types of transport measure. Table B2, in Appendix B, shows the middle half of the sample of output elasticities with respect to market access has values between 0.023 and 0.127, and the mean (median) value of the output elasticity is 0.08 (0.06) indicating that an increase of 10% in market access is associated with an uplift of firm output of 0.8% (0.6%). If we consider instead the effect of reducing distance to the transport network, Table B2 shows that the middle half of the sample has values between -0.027 and 0.006 , while the mean value is substantially influenced by whether we include the top and bottom percentiles. Taking the median as the reference point, we observe that reducing the distance to the nearest access point to the transport network by 10% is associated with an increase in output of around 0.14%.

Measuring the Effect of Transport Improvements: From Distance to Generalized Travel Cost

The summary in Table B1 in Appendix B shows that the most common measure used to capture the effect of transport investment is based on the concept of market potential, for which there are several similar implementations (e.g., effective density, economic mass, etc.). The market potential of a given firm in a given location is obtained by summing the opportunities for interaction in all

other locations and weighting them by (a function of) the distance, travel time, or generalized travel cost to access them. This approach is an improvement on the more simple measures used by macroeconomic studies, including a binary indicator of the presence or absence of a transport infrastructure within a given location (e.g., whether has railway station, whether is crossed by motorway), the amount of transport infrastructure (e.g., kilometers of railway, kilometers of motorway, number of radial roads), or transport investment. Although market potential type measures have become increasingly common in the literature, they often define transport costs using straight-line Euclidean distances that do not reflect the real transport network and cannot be used for time series analysis. Consequently, they cannot capture changes in the real transport network, but only changes in the spatial distribution of opportunities. Table 1 shows that evidence from microeconomic studies based on market potential type measures defines *access* in terms of Euclidean distances, while there is limited evidence from time-varying travel time (i.e., accounting for changes in the network) and the more comprehensive generalized travel cost. Fig. 2 shows the mean value of the output elasticity for market potential measures and definition of transport network. On average, the effect of transport accessibility on firm output appears to be stronger when based on generalized travel cost (i.e., accounting for both distance and travel time) and lowest for time-invariant travel time (i.e., assuming the transport network is fixed over time). One obvious limitation of the empirical literature is its exclusive focus on the road network, ignoring the other transport networks such as railways and urban mass transit.

Identification Issues and Strategies

There are three main identification problems faced by the empirical literature interested in the causal effect of transport accessibility on firm output and productivity. First, there can be spatial sorting bias because more productive firms may self-select into locations with better transport networks. The second problem is the nonrandom allocation of transport infrastructure across locations, that is, investment may be assigned to alleviate bottlenecks of higher productivity areas or/and encourage the growth of lower productivity areas. Finally, there can be other, omitted, factors that explain both better transport accessibility and higher firm productivity (e.g., urbanization level and type of industrial specialization). All three cases result in endogeneity bias and lead to inconsistent estimates of the transport effect.

While the use of firm fixed-effects can control for time-invariant unobserved heterogeneity (e.g., manager ability) influencing both productivity and choice of location, it does not address the problem of simultaneity bias. The latter has typically been addressed through instrumental variables (IV), whereby instruments need to be relevant (i.e., correlated with transport endowment) and orthogonal (i.e., uncorrelated with firm output and productivity). Currently, the most popular approach is to use a combination of historical instruments (e.g., Roman roads, old postal routes, planned routes, and past settlement population) with geographical and geological instruments (e.g., proximity to rivers, soil fertility, terrain ruggedness). The combination of these types of instruments can address reverse simultaneity bias between productivity and market potential because it instruments the size of the local and surrounding areas (i.e., the opportunities for interaction) and the transport cost (i.e., distance, travel time) between them.

Although less common amongst firm-level studies, there are alternative identification approaches based on the “inconsequential units” strategy. The strategy works by comparing outcomes between two groups of units receiving the transport improvement, where one of the groups consists of incidental beneficiaries (e.g., locations between large cities) for whom the outcome status is uncorrelated with the transport treatment. Recent work by Gibbons et al. (2019) using ward- and establishment-level data for Britain used the variation in the changes in accessibility amongst firms located within 1–20 km from a given transport project as the identification strategy. The argument used by the authors is that while the location of transport schemes is likely to be endogenous, the variation in accessibility experienced by firms close to the transport improvement is not. Under this assumption, they can then calculate the average causal effect of accessibility on firm labor productivity by comparing the outcomes of establishments located

close to transport schemes, after controlling for unobservable heterogeneity for each scheme and local (i.e., ward-level) characteristics. A similar approach has been used by studies using more aggregate spatial data (e.g., municipalities in Spain, districts in India) whereby locations with motorway nodes are treated as endogenous, while non-nodal locations in the vicinity of the nodal ones are taken as exogenous and their outcomes can thus be compared with those of non-nodal locations located further away (e.g., [Martín-Barroso et al., 2015](#)).

Table 2 compares output elasticities of transport accessibility between studies depending on whether they use IV or not. A tentative conclusion from the evidence in the table is that correcting for simultaneity bias revises the magnitude of the elasticity estimates downward for market potential type accessibility indicators, while the impact is less clear for measures of transport accessibility based on the distance to nearest access point to the network. The mean (median) value of the output elasticity with respect to market potential is 0.083 (0.064) for non-IV studies compared to 0.045 (0.047) for IV studies.

Industrial Heterogeneity

The scope for productivity effects from transport improvements is also likely to vary across industries due to differences in the relative importance of proximity to input (both primary and intermediate) and output markets. Here too, there is a clear linkage to the role played by urban agglomeration economies, in particular, by raising productivity through labor market pooling, input sharing, and knowledge spillovers. Existing evidence shows that knowledge intensive and high-skill sectors benefit more from central city urban locations compared to other service sectors and manufacturing industries, and thus may also benefit comparatively more from transport improvements. **Fig. 3** shows the mean value of the output elasticity with respect to market potential for all industries and the more aggregate economic sectors, while **Table 3** considers a more disaggregate breakdown of industries. On average, and in

agreement with economic theory, the productivity gains from transport improvements are positive and larger for services, followed by construction and manufacturing, and are negative for the primary sector.

Spatial Heterogeneity

Given the network nature of transport infrastructure, there can be scope for cross-border effects affecting both connected and non-connected areas. The nature of these effects is not a priori straightforward and will depend on complex local area characteristics, which can be either supported or hindered by better transport connections. New Economic Geography (NEG) arguments based on the core-periphery model with labor mobility find support from empirical evidence showing that reductions in interregional transport costs can encourage relocation of firms and people from more peripheral and poorer regions to more developed urban regions with some variation across industries depending on the degree to which they are likely to benefit from agglomeration externalities. Consequently, the overall regional impact of transport improvements is likely to depend on the local economic structure.

There are very limited number of microeconomic studies investigating the nature and scope for spatial effects of transport improvements on firm output and productivity. [Graham and van Dender \(2011\)](#) and [Holl \(2016\)](#) are some of the exceptions. [Graham and van Dender \(2011\)](#) tested for heterogeneity in accessibility effects across subsamples for British conurbations, big urban areas (250,000 people or more), and large urban areas (100,000 or more people) using semiparametric techniques. They found evidence of nonlinearities in the productivity–accessibility relationship, and that for conurbations and big urban areas higher market accessibility was not systematically associated with increased productivity, while the relationship was positive and significant for large urban areas.

[Holl \(2016\)](#) investigated whether firm total factor productivity effects from improved highway access differed across the urban hierarchy and found no significant highway effects on productivity for firms located in rural municipalities, while in suburban municipalities firms with access to a highway within 10 km (10–20 km) had productivity gains 18% higher (16% lower) than more distant firms (i.e., more than 20 km from the nearest new highway). She interpreted this result as evidence of negative spillovers in suburban municipalities: while the productivity of highway firms (<10 km) benefited from improved highway access, the productivity of adjacent firms (10–20 km) was hindered by it. Furthermore, firms in urban municipalities also showed a positive productivity-highway access effect, but it was weaker (i.e., 11%) compared to firms in suburban municipalities.

Overall, and so far, the existing literature provides very limited knowledge on the scope for spatial spillover effects from transport improvements on firms' productivity, and the degree to which they are determined by firm selection and relocation (i.e., entry and exit) mechanisms. Evidence from the literature studying the relation between transport accessibility and the spatial organization of economic activity suggests that within large cities and metropolitan regions (intra-regional) relocation is likely to be as important as urban growth and new activity creation, while intercity and interregional effects from transport improvements are more likely to result from displacement of activities from peripheral regions to more central ones.

Conclusions

There is growing evidence from microeconomic studies on the effect from transport improvements on firm output and productivity. Compared to more aggregate macroeconomic approaches, these studies tend to use more realistic measures of the transport network and how changes made to it impact on firm-level accessibility to economic opportunities. They also present advantages in terms of the empirical identification strategies that can be implemented to address issues of spatial sorting and simultaneity bias, which hinder causal inference in this literature.

This review proposes a number of tentative conclusions about the effects of transport improvements on firm output and productivity. It is common practice to use market potential type measures of transport improvements, which reflect the extent to which changes in the transport cost improve access to economic opportunities around firms' location. However, transport cost has often been measured with physical distance or time-invariant travel time instead of real transport network travel times, and the evidence reviewed shows that this choice can affect results. Many studies have attempted to address identification issues relating to firm self-selection and reverse causality by using a mix of approaches, ranging from firm-level fixed-effects estimator, instrumentation based on historical, geographical, and geological instruments, but also, although to less extent, some form of the "inconsequential units" strategy. The evidence shows there is considerable heterogeneity both between and within main economic sectors, with overall effects higher for services, followed by construction, manufacturing, and primary sector industries. With regard to the scope for spatial effects from transport improvements, there is still limited evidence on the degree to which the effect of transport improvements on firms' productivity results from firm selection and relocation and/or growth effects and this relation play out across different areas depending on their characteristics, including the development stage of the transport system. Evidence from the related literature on the relationship between transport and the spatial organization of economic activity suggests that within large cities and metropolitan regions (intra-regional) relocation is likely to be as important as urban growth and new activity creation, while intercity and interregional effects from transport improvements are more likely to result from displacement of activities from peripheral regions to more central ones.

There are important challenges needing attention from scholars. With respect to the measurement of transport accessibility, and although there has been substantial improvement, future research needs to consider transport networks beyond roads, in particular

railway and urban mass transit networks. This presents several data-related challenges but cannot be overlooked, especially within metropolitan areas and large cities. While railways can support higher density and less dispersed urban arrangements, motorways tend to promote suburbanization, which in turn can reduce the scope for urbanization economies. While there are several studies of the effect of railways on the spatial organization of economic activity and relocation effects, we lack studies of its effects on firm output and productivity. In addition, the literature has devoted insufficient attention to the study of the spatial effects of transport improvements on firm output and productivity, and how much of the overall net effect is explained by relocation or new growth. Does better transport make all firms more productive or does it improve the productivity of the fittest (selection) and attract more productive firms which replace older less productive ones (displacement)? How do these effects play out across different industries and regions? A better understanding of these complex dynamics is important, not only from an academic perspective, but also from a policy perspective.

Introduction

The economic impacts of transport improvements can be classified into three types. First are the direct benefits of the improvement in terms of vehicle operating costs, timesavings, and other benefits to existing and new users, together with the costs of noise and pollution produced. Second are the economic benefits deriving from better connectivity, holding constant the spatial distribution of economic activity; for example, the flow of knowledge between places may improve with benefits for productivity. Third are the changes in the location of economic activity arising as transport improvements change the spatial pattern of private sector investment; new investments may be induced in some places, possibly at the expense of other places.

A standard cost–benefit analysis (CBA) focuses on the first of these. This is not because analysts are unaware of the other impacts, but because analysis of a project is generally set in the context of a wider economy with few or no externalities or other market failures.^a In such an economy changes in quantities, such as new patterns of investment, are of zero social value; the marginal benefit of an activity is equal to its marginal cost. The terms “wider economic impacts” or “wider benefits” are used to describe the second and third types of effects and are the subject of this paper.

Analysis of the effect of transport investments has to contain two elements. One is to establish the quantity effects of the improvement; this means the changes in economic quantities—numbers of journeys made, new investments undertaken, and jobs created—arising because of the investment. This assessment may need to be quite broad because creation of a job in one place may be at the expense of a job lost somewhere else; establishing whether relocation and displacement effects of this type occur is crucially important. The other is to place a social value on these quantity changes; this is relatively straightforward if everything is traded at fixed prices in competitive markets, and more complicated otherwise.

To explore these issues this paper proceeds in three stages. The next section offers a brief review of some of the elements of spatial economics, fundamental to transport investments. Section “Wider Impacts I: Connectivity and Productivity” looks at wider impacts arising from changes in connectivity and productivity, given patterns of land-use and the spatial distribution of activity. Section “Wider Impacts II: Induced Private Investment and Land-Use Change” looks at ways in which transport improvement can induce changes in private investment and land-use, and at the value of any such changes. Throughout, the focus is on identifying and quantifying wider impacts for the purpose of ex ante appraisal of transport investments. The literature on ex-post evaluation of investments is reviewed in Redding and Turner (2015).

The Spatial Context

Economic activities are spatially “lumpy”, tending to concentrate in space. This is partly due to the minimum efficient scale of some business activities (e.g., large factories that supply a wide geographical area) and partly due to agglomeration economies. These arise if there are complementarities and increasing returns to scale operating across a range of firms and workers who are in close proximity to each other. They are driven by a number of mechanisms. Large local labor markets enable better matching of workers to firms’ skill requirements. Better communication between firms and their customers and suppliers enables knowledge spillovers, better product design, and timely production. A larger local market enables development of a larger network of more specialized suppliers. Fundamentally, larger and denser markets allow for both scale and specialization, thereby creating areas of relatively high productivity.

^aThere is an extensive literature on market failure and externalities within the direct context of the project itself. Imperfections in labor markets and in international trade policy were central to an older literature on shadow pricing in developing economies (Dreze and Stern, 1987).

Agglomeration economies typically involve externalities between firms, and between firms and workers. To take one example, the larger the market, the more likely it is to be worthwhile for an individual to specialize and hone skills in producing a particular good or service, thereby achieving high productivity. The specialist will be paid for the product or service supplied but, depending on market conditions, is unlikely to capture the full benefit created.^b Since the benefit is split between the supplier and her customers, there is a positive externality. This creates a positive feedback—more customers will be attracted to the place to receive the benefit, growing the market, further increasing the returns to specialization, and so on. This is the classic process of cluster formation.

The spatial and sectoral range of agglomeration economies varies according to the context. They are important within particular sectors, particularly those prone to cluster (e.g., financial services and high tech) and are referred to as localization, or Marshall–Romer economies. They also operate at a wider urban level, referred to as urbanization or Jacobs economies.

Agglomeration economies are a benefit, but proximity also has costs, particularly in the urban context. Clustering of firms increases commuting costs for workers who may have to travel far to employment centers such as the central business district. These costs are exacerbated by congestion—a negative externality—and other costs of dense urban living. Land becomes the scarce factor and housing consumption (floor space per household) is reduced. However, it is important to note that high land rents and land prices are not a real cost; these are a transfer payment from occupants of land to its owners, so do not use up real resources (as does time in commuting).

The location of economic activity is determined by the interplay between the benefits and costs of proximity, together with location fundamentals (including “first-nature” physical geography). Since agglomeration effects are largely externalities, location outcomes are generally not efficient, and there may be situations in which a place is stuck in a low-level equilibrium. These facts create the potential for transport improvements to be “transformational,” bringing large quantity changes and perhaps also large welfare gains. We will discuss these effects in section “Wider Impacts II: Induced Private Investment and Land-Use Change,” but note that they are, in practice, extremely hard to predict. The practical literature applying wider benefits to the practice of CBA has largely taken a more conservative route, looking at improvements in connectivity given the location of activity and the pattern of land-use. It is to this that we now turn.

Wider Impacts I: Connectivity and Productivity

Transport investments make places closer together, in economic terms, potentially increasing productivity, thereby also creating a wider impact. To capture this, a quantitative measure of the importance of agglomeration economies is needed, and many studies have produced estimates.^c A simple approach to this quantification involves two steps. First, compute a measure of the economic scale and density of a place, and, second, regress productivity on this measure. Scale and density are typically calculated by a measure such as “effective density” defined as $ED_i = \sum_j f(d_{ij}) \text{employment}_j$. This says that the effective density of place i is the sum of employment in other places, j , weighted by an inverse function of the distance between i and j , d_{ij} , with $f(\cdot)$, a decreasing function. At the second stage, the elasticity of productivity with respect to effective density is estimated, typically by regressing productivity in each place on its measure of effective density and other factors.

Doing this across cities, the first finding is that the elasticity of productivity with respect to city size is of the order of 0.05–0.1. Thus, a city of 5 million inhabitants typically has productivity of 12%–26% higher than a city of ½ million. This raw number has been refined in many directions, the literature on which is surveyed by [Rosenthal and Strange \(2004\)](#) and [Combes and Gobillon \(2015\)](#). For example, measured productivity depends on the skill and occupational mix of the labor force in each place. Controlling for observed measures of skill (e.g., education) typically brings the elasticity down by about a quarter. This might only be part of the story, as there may be sorting, meaning that people with higher innate ability (regardless of education) are disproportionately drawn to cities. The only way to observe this is to track individuals as they move in to cities or to cities of different sizes. Recent empirical work doing this suggests that the pure agglomeration effect has elasticity of 0.02–0.04. This is still a substantial number.^d

This framework has been applied to transport appraisal, notably in the WebTAG guidance of the UK Department for Transport. A transport investment that cuts journey times reduces effective economic distance between places, d_{ij} , and hence (given employment) increases the effective density of such places. This raises the productivity of *all* workers in these areas according to the estimated elasticity of productivity with respect to effective density. The productivity increment is a welfare gain that is added to the user-benefits derived from a standard transport CBA. These “wider benefits” can amount to around 15%–25% of the total net benefit of a large transport project.

The approach constitutes a well-grounded attempt to add some wider impacts in a rigorous and contained manner, although a number of further issues remain. Application of the method is sometimes mechanical, with little attention to context. There

^b This example is a pecuniary rather than a technological externality, that is, an effect transmitted through an imperfect market. The supplier will capture the full benefit only if able to perfectly price discriminate. Otherwise, the customer will also receive some consumer/user surplus on the introduction of a new product. This observation is central to the wide-range of economic models in which the number and variety of goods and services offered is endogenous.

^c Methods and data sources vary widely, and are surveyed in [Gibbons and Graham \(2018\)](#).

^d In some contexts, it may not be appropriate to impose all these controls. Suppose that someone achieves high productivity by undertaking education to acquire a skill that is in demand only in large cities. Then both the city and the education are necessary for attaining the productivity, and it would be wrong to attribute it all to education ([Combes and Gobillon, 2015](#)).

are further measurement issues, as the strength of localization economies varies by sector, and the spatial range of effects is important (i.e., the form of the function $f(\cdot)$, for example, see [Gibbons and Graham \(2018\)](#) or [Rice et al. \(2006\)](#)). Further problems arise if a transport investment only effects one mode of transport; for example, a rail improvement may only affect a small proportion of total journeys made between two places, so calculation of its impact on an overall measure of “economic distance” is controversial.

Wider Impacts II: Induced Private Investment and Land-Use Change

Large transport improvements generally change the spatial pattern of private investment and hence jobs—indeed, this is often the motivation for undertaking the improvement. Estimating these quantity changes, *ex ante*, generally requires modeling techniques such as computable spatial equilibrium models or land-use transport interaction (LUTI) models. These provide useful quantitative frameworks and can indicate a range of possible outcomes, although they are far from precise predictions. Studies of past transport improvements provide further information, but are fraught with statistical problems.^e There are problems of endogeneity (is a region booming because a road was built, or was the road built because the region was expected to boom?), selection of appropriate control areas, and of distinguishing net aggregate growth from spatial relocation. Above all, there is the problem of context specificity; what we learn from previous transport investments may or may not be relevant to the context of a particular new investment.

Given estimates of quantity changes, the task is to ascribe them social values. The benchmark is “small” changes in a “perfect” economy, in which case the net value of quantity changes is zero. We move beyond this case in several steps, progressing from “small” changes, that is, those that leave prices in affected places broadly unchanged, to large ones.

Market Imperfections and “Small” Changes

Why is it socially valuable to create a job in a particular place, even if it may involve losing a job elsewhere? One answer is that there is involuntary unemployment, so creating a new job expands the total number of people in employment, rather than just relocating jobs. Another is that there are spatial income differentials, so social welfare increases if a job moves to a low-income area. A third is that there are factors that “distort” individuals’ choices about labor-leisure decisions, or about choice of place of work.

An example of the last of these arguments, included in the UK Department of Transport appraisal procedures, is the move to more (or less) productive jobs. This can arise if there are productivity differences between places within a city (or between regions in the country) and a transport improvement causes an increase in employment in one area and a decline in another. Thus, in the intra-urban context, it may be the case that productivity is higher in the city center than at the city edge. This can be an equilibrium, as the combination of commuting costs and high city-center house prices means that individuals are indifferent between taking a high-wage and high-productivity job in the center and a lower wage job at the edge. An improvement in commuting transport infrastructure that leads to more people working in the center raises average productivity but does not necessarily create a net benefit; there is no such “wider benefit” if individuals’ job and location choices are efficient.^f The change only has nonzero value if there is some market failure or distortion that makes private choices inefficient. One such distortion is income tax. Individuals’ choice of place of work depends on posttax income, not pretax (which reflects productivity). It turns out the net social gain from moving people to higher productivity jobs is exactly equal to the additional income tax revenue raised as a consequence of the move.

Price Change and Transfer of Surplus

Transport improvements may trigger “large” changes in investment and activity in an affected place, as with the development of new urban subcenters or attempts to rebalance regional economies. Large developments will change prices, and it then becomes important to understand the effect to which such changes are, or are not, internalized in developers’ decisions. Land value appreciation in the immediate vicinity of the project can be internalized by ownership of the land, but the development might also change land prices over a wider area (perhaps reducing them elsewhere). The development might also reduce prices of goods and services if there is an increase in their supply, or bid up the wage rate if employment expands. If these changes impact on people and firms other than the project developer then there is a divergence between the private and social returns from the development; higher wages or lower prices caused by the development are a benefit to those who receive/pay them, but not to the developer. This divergence means that the development—the indirect quantity change induced by the transport improvement—has nonzero social value.

Implications are illustrated in [Fig. 1](#). The horizontal axis is the cost, t , of accessing a potential new development site (e.g., transport costs borne by customers or employees). If this is very high the development is not undertaken—both private (developer) and social returns are negative, as measured on the vertical axis and indicated by the solid lines.^g Improving access (reducing t) increases both private and social returns. Initial access costs are at point A, and they are reduced by amount Δt by a

^e A good example of this work is [Donaldson \(2018\)](#), and see [Redding and Turner \(2015\)](#) for a review of modern approaches.

^f For purposes of this argument, productivity levels are assumed to be exogenous and fixed. See [Venables \(2007\)](#) for a more general case.

^g In [Fig. 1](#), these are the social returns associated with the price and wage change not those in the standard CBA, which can be thought as being in *net* cost $C(\Delta t)$.

Figure 1 Transport improvement unlocking development.

publicly funded transport investment with net cost $C(\Delta t)$ (larger the greater the transport cost reduction). At initial point A the development is not undertaken; private returns are negative, although social returns are positive, the divergence between the two arising from the price or wage change effects is discussed earlier. A transport improvement reducing access costs to point B ($\Delta t = A - B$) would be just sufficient to trigger the development, yielding “wider benefit” $S - B$, an amount that should be added to a conventional narrow CBA.

In summary, the fact that the development is “large” means that the initial point A is inefficient. Transport improvement is a (second best) way of removing the inefficiency, and thereby creating social gain. This is a “wider impact” of a transport improvement that unlocks development potential.

Agglomeration and Coordination Failure

In section “Wider Impacts I: Connectivity and Productivity,” we saw that transport improvement could raise productivity by increasing effective density; even if economic activity does not move, places become closer in terms of travel time and economic distance, d_{ij} . However, transport improvements generally induce changes in the location of activity that will lead to further productivity. Using the framework set out in section “Wider Impacts I: Connectivity and Productivity,” effective density and hence productivity will change as the terms $employment_j$ in the expression for ED_i change.^h Thus, if a transport improvement—for example, an increase in commuting capacity—enables employment in a cluster of activity to grow then, in the presence of agglomeration economies, the productivity of workers in the cluster (existing workers as well as new) will increase. This has been an important argument informing decisions to improve commuting into city centers, although it is subject to caution for the usual reasons of displacement. If workers are just moving from one cluster to another then the productivity gains in the growing cluster may be cancelled out by losses in the other.ⁱ

A more fundamental issue arises as transport improvement may have as its objective not just to move investment and employment into an area, but also to trigger the establishment of a new cluster of activity. There are important market failures associated with establishing new clusters, deriving from the fact that agglomeration economies are positive reciprocal externalities; firms and workers in a cluster create and receive benefits. This creates the first-mover problem; no one wants to be the first to move to a new place unless they are confident that others will follow. Expectations of future returns are critical (particularly since location decisions are generally long-lived and incur sunk costs), and these depend on who else is (or is expected to be) there. Success requires that expectations are coordinated—so each firm knows that each other firm will move. Absent this, there is “coordination failure.” The private benefit of moving is less than the full social benefit so investment will not take place, similar to being stuck at point A on Fig. 1.

What is the contribution of transport to this? Many conditions have to be met for a place to become attractive for new investment, and it is hard to argue that reducing transport costs alone is sufficient to trigger development of a new cluster. However, a transport improvement can play an important role in coordinating expectations, over and above any transport cost reductions that it may bring. For example, consider a growing city in which it is clear that a new subcenter would be profitable, but there are many potential sites for such a center. If no one knows which site will develop, then no one will invest; the challenge is therefore to create a credible signal that will coordinate expectations. City plans are one instrument to achieve this, but their poor implementation record means that they are unlikely to be credible. Investment in infrastructure is an alternative, credible since such investments are sunk and irreversible.

^h Changes in effective density holding employment constant are sometimes referred to as “static clustering,” and those with employment changing are “dynamic clustering.”

ⁱ If there is full employment, then displacement implies $\sum_j employment_j = 0$. In some circumstances, productivity effects will exactly cancel; see Kline and Moretti (2013). However, they will not cancel out if agglomeration is driven by sector-specific localisation economies and cluster growth enables a high-agglomeration sector to expand.

Conclusions

There is often a tension between the strategic case made for a major transport improvement, and the economic case. The former is likely to be based on assertions about wider impacts, and the latter on a narrow CBA that implicitly ignores all such effects. It is important to develop a rigorous understanding, based on theory and evidence, of the mechanisms, circumstances, and magnitudes of any such wider impacts. This is needed both to make the arguments for wider impacts and to challenge spurious arguments that are sometimes made.

Progress has been made on the conceptual side, laying out the mechanisms through which wider benefits can occur, and in empirical work quantifying some key relationships such as the productivity benefits of density. More needs to be done, building on a variety of techniques including modern quantitative spatial modeling, both to get a better understanding of possible quantity changes brought about by transport investments and to ensure that these are valued in a full general equilibrium setting, where displacement effects are taken into account and the risk of double counting are minimized.

Introduction

It is well known that investment in transport infrastructure may have positive impacts on economic output. These arise as reductions in transport costs change the location of firms and residents, reinforcing agglomeration economies in those areas that benefit from the project, which in turn have positive effects on employment. The analysis of the impacts of transport infrastructure on the level and the localization of economic activities, as well as the discussion about whether they are a net benefit or just a transfer between areas, are dealt with in other parts of this Encyclopedia. In this chapter, we focus on the effects that a reduction in individual commuting costs may have on their labor market outcomes, particularly focusing on those workers more adversely affected by the physical disconnection from jobs. Commuting costs include both time and monetary costs of accessing the workplace.

Known as the spatial mismatch hypothesis, the analysis of the relationship between access to jobs and labor market outcomes has been a topic of debate in the North-American academic literature since Kain's (1968) seminal contribution. According to his original work, the process of employment decentralization that took place in the US cities like Chicago or Detroit since the 1950s led to a disconnection between residential and job location in the case of racial and ethnic minorities, especially for Afro-Americans, who mostly remained living in the inner city. Housing market discrimination against blacks prevented them from relocating closer to jobs. The underlying hypothesis in Kain's work is that the physical disconnection from jobs could be a key factor in explaining persistent unemployment among Afro-Americans.

Since then, a large number of empirical studies (see the surveys by Ihlandfeldt and Sjoquist, 1998 and Gobillon et al., 2007) have analyzed the relationship between different individual outcomes in the labor market (participation, hours worked, unemployment, or wages) and the characteristics of the place of residence. The latter are not limited to accessibility to jobs, but also include features related to residential segregation. The initial focus on Afro-American communities in the US cities has been extended in several directions. First, to include other disadvantaged groups such as low-educated workers, youth, and women. Second, to other metropolitan areas where sprawl has also taken place. The empirical results confirm that the spatial mismatch hypothesis is relevant in a large number of contexts. A related line of research considers that over-qualification with respect to the job requirements can also be the result, among other factors, of spatially constrained job search. Finally, while the first studies focused on the impact of car accessibility or car ownership, more recent work introduces public transport into the analysis.

Although the empirical work found evidence in favor of the existence of spatial mismatch, sustaining a causal relationship was made difficult by the lack of a theoretical framework and by different methodological problems related to the econometric estimation. More recent work has addressed these problems. On the one hand, theoretical models aimed at explaining spatial mismatch have been developed since the late 1990s. On the other hand, both the econometric methodology and access to better quality data have experienced substantial improvements that avoid biases and spurious relationships.

The rest of the chapter is organized as follows. In section, "Theoretical Framework" we summarize the theoretical framework for the spatial mismatch hypothesis, and in section, "Measure of Accessibility" we discuss the details underlying the measurement of accessibility. Section "Econometric Methodology" explains the econometric methodology and the main problems related to it. Finally, section "Results and Policy Implications" summarizes the main results and derives policy implications.

Theoretical Framework

It was not after the publication of a significant number of empirical papers that the theoretical mechanisms underlying the spatial mismatch hypothesis were developed in the context of urban labor market models (Brueckner and Zenou, 2003; Coulson et al., 2001; Wasmer and Zenou, 2002).

The development of such models made it possible to clarify how disconnection from jobs can result in poor labor market outcomes. Gobillon et al. (2007) provide a review of the mechanisms of spatial mismatch, which are related to both labor supply and demand. From the labor supply point of view, the theoretical logic can be based on either job search costs or reservation wages. Regarding the first explanation, job search efficiency may decrease with distance to jobs since information on job opportunities is lower for distant jobs. Additionally, the unemployed workers will incur increasing transport costs as distance increases and, accordingly, restrict their search to neighboring areas. The latter effect may be particularly important for those individuals dependent on limited public transport. The explanation based on reservation wages considers that potential workers may refuse job opportunities that require commuting costs that are too high in relation to their proposed wage. Therefore, reducing time and/or monetary costs of accessing to workplaces and their related information will increase the probability of finding and accepting a job.

The negative effects of distance can also be explained from the labor demand viewpoint. Given that, as shown by empirical evidence, workers that commute long distances may be less productive and have a higher rate of absenteeism, employers can be less willing to hire them, or will do so paying lower wages.

Therefore, improving accessibility to the workplaces through better transport can positively affect labor market outcomes by increasing search efficiency, reducing the reservation commuting cost, and improving labor productivity. These effects will enlarge the effective size of the labor market and have positive consequences on labor force participation rates; number of hours worked or wages levels, as well as reducing the length of unemployment duration.

However, distance is not the only spatial factor that may explain bad labor market outcomes. Residential segregation may also have an adverse effect through different channels. First, it can lead to labor market discrimination. As argued by Gobillon et al. (2007), employers may discriminate against residents in some specific areas on the basis that they presumably have bad working habits, are dishonest or criminal, although this argument is mostly related to some kind of ethnic discrimination. In the context of the US cities a large debate emerged on the role of race versus distance to jobs to explain the labor market results of the black population located in inner cities. The current consensus seems to be that both race and space contribute to spatial mismatch.

Second, residential segregation can amplify the negative labor market outcomes through neighborhood interactions. A disadvantaged neighborhood may generate lower incentives for young people to invest in education, partially as a consequence of the existence of peer effects at school level. This has labor market effects given that lower human capital investment adversely affects individual labor market outcomes. Besides, segregation causes a deterioration of information networks about jobs, which prevents people with low education and ability levels to benefit from social networking within the community. These arguments have to be understood considering that residential segregation is more related to job disconnection than to physical distance between job and residence locations. In other words, residential segregation does not necessarily increase with distance.

Finally, research on spatial mismatch shows that distance to jobs affects population groups differently, with larger effects in the case of more disadvantaged groups. The literature shows that accessibility is especially important for, among others, unskilled, female, younger, and older workers. The reason why the underlying mechanisms for spatial mismatch have a different effect on a particular group can be explained by how constrained they are by local job opportunities. For instance, in a context of decentralized employment and residence, private vehicle may sometimes be the only available option for accessing workplaces. If that is the case, those groups that have to rely on poor public transport will be constrained to accept local jobs.

In summary, after several decades of research the spatial mismatch hypothesis can be grounded on different theoretical models. However, the magnitude of the contribution of accessibility to labor market outcomes remains an empirical question. In what follows we try to shed some light about the methodological approaches used, the main challenges faced by research in this area and the results obtained.

Measure of Accessibility

There are different methodological issues related to the empirical definition of accessibility measures when testing the spatial mismatch hypothesis. As some authors have pointed out (see Houston, 2005 for a survey) methodological choices may lead to significantly different results. Following Bunel and Tovar (2014) the choices that have to be made when measuring labor market accessibility in this context can be grouped around the following issues:

The Role of Distance

When dealing with the question of which is the impact of geographical distance on job accessibility, the answers fall between the extreme cases, which consider that space is frictionless (and there is a single labor market within which all jobs are equally accessible) or regard distance as an insurmountable barrier (and the labor market is strictly local). In between those (probably irrelevant) cases, different varieties of distance-decay functions can be used to show how accessibility decreases as distance increases. Although taking straight-line distances may appear to be a logical simplification of the problem, it would in fact understate real distances

proportionally more in the case of shorter trips and, as a consequence, it would bias the results against finding evidence in support of the spatial mismatch hypothesis.

A related problem to that of modeling distance is how to deal with the so-called 'frontier effect,' which arises in empirical work when the area under study is geographically truncated, and thus makes it possible that the labor market extends beyond its limits for workers or jobs located sufficiently close to the border. Using French data, [Bunel and Tovar \(2014\)](#) compare accessibility measures obtained at the national scale with those limited to the Paris region. Although the overall measures do not differ by much, there are significant differences for border municipalities.

Transport Mode Choice

The same geographical distances will be subject to different commuting generalized costs depending on the transport modes being available and their service characteristics (including frequencies, congestion, reliability, etc.). Taking into account the ability of different individuals to use different modes leads to the need to consider mode choice models (including decisions on car ownership) that will reveal the importance of individual attributes in the valuation of each mode. The empirical literature has shown that different social groups may have different propensities to commute and that income levels will play a particularly important role in mode choice, given their correlation with values given to travel time savings.

Matching Workers and Job Vacancies

When matching jobs with workers, individual characteristics of both sides matter. Again, this can be simplified in an extreme way assuming that any job could be open to any worker. It is however more realistic to consider that jobs of specific characteristics will be available only to workers with the required educational or skills level. Of course, the level of detail of the specific job-worker matching will depend on available data on both the skill/education requirements of jobs and the workers' endowments, but ideally it would also be necessary to consider the possibility that workers access jobs for which they may be overqualified. When analyzing the spatial mismatch of particular disadvantaged groups, assumptions need to be made to identify the specific job market segments for which they compete, which need not to be the same as those of the overall population.

Vacancies and Competition for Them

Although in the previous paragraphs we have referred to access to jobs, it is clear that what matters to measure accessibility is the location of actual vacancies. However, given that the latter may not be easily observable, a simplifying assumption is often made about location of jobs and vacancies being highly correlated. Related to this, any accessibility measure for vacancies also needs to take into account the potential competition that may exist between workers to occupy them, so vacancy accessibility for a given worker will depend on the number of potential workers who may also access to it. Therefore, when computing an accessibility index, each vacancy should be indirectly weighted according to the pressure that competing workers put on it. This is done by including in the index a measure of accessibility to the vacancy by other workers, in a way that considers vacancies with more rivalry as less accessible.

Labor Market Flexibility

Given the increasing flexibility of the labor market, both the existence of multiple part-time jobs or the lack of proper definition of the location of certain vacancies creates additional challenges for defining and measuring accessibility. Workers on part-time employment looking for an additional job will face accessibility conditions that do not depend only on their residential location. Although in the case of jobs that make it possible to work from home most accessibility issues may seem to be irrelevant, there will still be some need to access certain locations for specific tasks, requiring to define accessibility accordingly.

Econometric Methodology

The most common approach to empirically test the spatial mismatch hypothesis is to relate a measure of labor market outcome to an index of job accessibility controlling for a set of additional explanatory variables, in the form of an econometric model whose parameters can be estimated. Whereas some studies use individual data, others employ aggregate data defined at some detailed spatial level. Although cross-section data is predominant, a growing number of researchers employ longitudinal (panel) data. The econometric specification of different studies vary according to the nature of the dependent variable -discrete, censored, or continuous- and the way they deal with different econometric methodological problems.

In order to identify the role that accessibility plays in terms of labor market outcomes, it is necessary to disentangle the effect of distance to jobs from other spatial and non-spatial factors that may also have labor-related impacts. The equation's specification must, therefore, include a rich set of explanatory variables to control for personal and neighborhood characteristics. The latter play a particularly important role since they control for spatial segregation, which, as already explained, may also be related to employment outcomes. Given the importance of defining these variables at small spatial units, using census tract information has become common practice.

A potentially important problem faced by the proposed econometric strategy is that of the endogeneity of the accessibility variable, which may be caused by two effects. A problem of simultaneity arises when job accessibility influences the result in the labor market, but through residential sorting processes the reverse is also true. Besides, there may be unobserved individual characteristics (for instance, different individual productivity levels) that simultaneously affect both neighborhood location and labor market performance. In both cases, the accessibility index will be correlated with the random error term of the equation and, consequently, the estimates of the effect of job accessibility will be biased. Different strategies have been proposed to deal with this endogeneity problem.

One way to obtain consistent estimates is to use instrumental variables. The underlying idea is to find a variable or set of variables strongly correlated with the explanatory variable (in our case, job accessibility) and, at the same time, with no direct effect on the dependent variable (that is, independent of the random term of the equation). In this way it is possible to extract the exogenous source of variation in the accessibility variable to assess its effect on labor market outcomes. Sometimes the lagged values of the same explanatory variables are used as instruments. However, this is not an advisable option since lagged values will generally also be correlated with the error term. The difficulties in finding instruments that fulfill the necessary requirements have led researchers to look for alternative solutions.

A second approach to deal with endogeneity is to rely on natural or quasi-natural experiments. The idea in this case is to use a situation where the residential location of individuals can be considered as exogenous. Although there are not many such situations, a growing number of researchers are exploiting this idea from different perspectives.

[Aslund et al. \(2010\)](#) make use of a refugee dispersal policy by which the Swedish government assigned refugees to neighborhoods with different degrees of geographic job accessibility. Therefore, individual residential location could be considered exogenous. Moreover, since all individual characteristics used to assign the refugees were observed by the researchers, any excluded individual variable will be uncorrelated with the measure of job accessibility. In this context, the researchers find that having been placed in a location with poor job access adversely affected employment.

[Andersson et al. \(2018\)](#) overcome the methodological limitations by using employer-employee matched data on workers searching for jobs after a mass lay-off. They focus on workers with strong labor attachment who experienced a displacement, resident in different US states adjacent to the Great Lakes. In this case, job searching reasons can be considered exogenous and not related to local job opportunities. Their rich data set make it possible to identify transitions to new jobs as well as to construct personal job accessibility measures and control for demographic and neighborhood characteristics. Their results support the spatial mismatch hypothesis: better job accessibility significantly decreases the duration of unemployment among low-medium income workers. The effect is especially important for blacks, women, and older workers.

Other papers base their quasi-experimental approach on the construction of a new transport infrastructure that can be considered exogenous to individuals' labor market outcomes. The research methodology, known as difference-in-difference (diff-in-diff) consists in comparing, before and after the construction of the infrastructure, the outcomes in the same local labor market of those who benefit from the infrastructure improvement (treated group) from those who do not (untreated group). Data requirements of this methodology are demanding. First, it is necessary to observe individual outcomes before and after the change. Second, information is needed to control for all those characteristics not related to the transport improvement that might differ between the treated and the untreated groups. The robustness of this type of analysis crucially depends on the new infrastructure being exogenous and on controlling for differences among groups other than their accessibility. Some examples of this approach are [Holzer et al. \(2003\)](#) who exploit the construction of a new railway line in the San Francisco Bay Area to evaluate accessibility improvements to jobs in the case of minority workers, [Sari \(2015\)](#)'s investigation on the impact of a new tramway in specific neighborhoods in Bordeaux and [Aslund et al. \(2017\)](#), who assess the effects of the introduction of a commuter train to the employment center in Uppsala.

Other papers restrict their analyses to sub-groups of population whose residence can be considered exogenous with respect to the characteristics of the local job market. An example are young adults still living with their parents ([Raphael, 1998](#)). However, this is an imperfect approximation since the unobserved characteristics of the young adults may be correlated with those of their parents and, therefore, be related to residential location ([Gobillon and Selod, 2014](#)).

A third possibility is the use of longitudinal data to soften the endogeneity problem caused by unobserved individual characteristics that are correlated with both the labor market outcomes and the residential location. Controlling for individual fixed effects can capture those unobserved factors that are common to the individual but do not vary over time. Using this approach [Weinberg et al. \(2004\)](#) conclude that estimates that do not correct for endogeneity overstate the effect of neighborhoods but understate the effect of job accessibility, because individuals with lower employment probabilities are located around central business districts. Given the difficulties of gathering individual longitudinal data, some researches rely on spatially aggregated data and compute average values for the variables at small neighborhood areas. However, when using longitudinal data two issues have to be considered. First, the temporal dynamic adjustment of the model must be taken into account. Second, it is crucial to separate the effects of investment in infrastructure from the effects of changes in the location of the workplaces. These are not always easy tasks.

A last methodological issue worth mentioning is the endogeneity of car ownership. As it has already been mentioned, car availability influences labor market performance but, at the same time, the decision of owning a car is clearly related to labor market outcomes. In order to deal with this simultaneous relationship some authors use instrumental variables while others estimate vehicle ownership and mode choice models.

Results and Policy Implications

After several decades of empirical and theoretical research, there is enough evidence to confirm that poor accessibility to jobs leads to worse labor market outcomes. Advances on the theoretical framework, the econometric methodology, the definition of accessibility measures and the quality of available data have resulted in more reliable results. As an example that combines these features, the recent paper by [Andersson et al. \(2018\)](#) provides robust evidence on the negative effect of accessibility on unemployment duration among low-paid displaced workers for a subset of metropolitan areas in United States, with an especial effect for blacks, women, and older workers.

From the initial studies focused on labor market performance of disadvantaged workers in the US cities, the empirical research has extended into a wider set of cities in Europe ([Patacchini and Zenou, 2005](#) for England; [Aslund et al., 2010](#) and [Norman et al., 2014](#) for Swedish cities; [Matas et al., 2010](#) for Spanish cities; [Korsu and Wenglenski, 2010](#) for Paris-Île-de-France and [Sari, 2015](#) for Bordeaux) and beyond (see the analysis by [Boisjoly et al., 2017](#) of accessibility and informality in Sao Paulo, Brazil, or [Rosbapé and Selod, 2006](#) of unemployment in Cape Town, South Africa). Moreover, whereas the initial focus was on car availability, the role that public transport may play in offsetting the adverse effects of disconnection has received increasing attention ([Holzer et al., 2003](#)).

However, not all researchers find a clear relation between accessibility and employment outcomes. [Cervero et al. \(2002\)](#), [Sanchez et al. \(2004\)](#), [Dujardin et al. \(2007\)](#), or [Aslund et al. \(2017\)](#) did not find such evidence in different contexts.

The overall conclusion that emerges out of the research outputs in this area is that transport policy can contribute to improve labor market outcomes by increasing accessibility, but it does not guarantee that just any infrastructure project will do so. Moreover, the positive effects can be expected not only from investment in private transport infrastructure but also by improving public transport provision. This last result is important on the light of the negative externalities generated by the use of car. Besides, disadvantaged workers will benefit most from public transport improvements since the effects are higher for less-skilled individuals and those with weaker labor attachment, since they are more constrained to local labor market opportunities.

Introduction

Public transport—or “transit” in the North-American context—(hereafter “PT”) is an umbrella term variously defined. This chapter focuses on collective modes of land passenger transport services available to the general public on a nondiscriminatory and continuous basis, and in most cases according to predetermined routes, timetables or frequencies and fares. The analysis comprises PT services offered within the metropolitan context (frequently referred to as local and regional public transport), and intercity transportation.

The organization and provision of PT has historically been at the center of academic and policy debates, and particularly so since the 1980s, as the sector witnessed significant and continuous regulatory reforms characterized and inspired by a wave of neoliberal thinking, many times connected to the label New Public Management (here after “NPM”). These reforms aimed at improving the efficiency and effectiveness of the public sector with the introduction of managerial practices typical from the private sector. In PT, this has been mainly characterized by a growing role for the use of competition, particularly through the competitive tendering of contracts, but also via market deregulation (Van de Velde, 2019).

As a result of the changes implemented in these decades, the sector, that before—in the European context—was typically made up of de facto area monopolies with ex post subsidization, is currently growingly organized under time-limited contracts that define exclusive rights, set service requirements and include various sets of financial incentives. Furthermore, large operators, often affiliated to state-owned railway companies, are increasingly active in markets outside of their country of origin. They have appeared alongside municipally owned operators, whereas the number of small, local businesses is decreasing.

The chapter proceeds by reviewing the rationale behind reforms occurred in the last decades, describing the main institutional setup options that have appeared since then, and defining typologies and basic reference models that support the understanding of how existing institutional frameworks work in practice. To conclude, the final section proposes initial reflections on the future direction of PT regulation in view of transformations in PT triggered by the appearance of new technologies and service models such as autonomous vehicles and mobility as a service (MaaS).

Why Reforming: Public Transport Performance and New Public Management

Finding the most appropriate regulatory framework to organize and provide PT services has traditionally occupied a prominent role in academic and policy debates. Chadwick (1859), already in the 19th century, compared the potential advantages and disadvantages of employing competition for the field—namely competition for having access to a market or area where to deliver PT services—and competition within the field—related to the competition between different transport providers operating in the same market. Similar discussions, involving various other organizational elements of PT, such as the allocation of risks between authority and operators, nature and ownership of operators, or ticket and fare integration have proliferated in recent decades (Hirschhorn et al., 2019; Pucher and Kurth, 1995; Roy and Yvrande-Billon, 2007).

The backdrop for these debates is the understanding that the way in which the production and delivery of PT services are organized may influence the achievement of performance targets. That is, PT is seen as a tool to enable the realization of a number of public values—the goals society expects government to achieve in a policy area (Jørgensen and Bozeman, 2007)—and organizing the sector appropriately can support political ambitions connected to aims like cost-efficiency, sustainability, or accessibility.

In the 1970s and 1980s, the rise of neoliberal ideals giving primacy to values like efficiency and effectiveness profoundly influenced public sector services. Reforms under the New Public Management label (NPM) introduced new practices in public administration advancing horizontal specialization in the public apparatuses, with the use of contracting, and implementation of a private-sector management style with explicit performance standards and output control. At the same time, on a vertical dimension, reforms emphasized structural devolution, and the creation of specialized agencies. According to the NPM proposition, policy making is separated from policy administration and implementation, and coordination in the production and delivery of public services is to be achieved through the market's "invisible hand" (Christensen, 2012; Hood, 1991).

In particular for PT, such approach targeted problems such as productive inefficiency, the undesirable growth of public subsidies and declining market share, all highlighted by a noninnovative or bureaucratic image of the sector. These reforms are interesting in light of cross-sectoral policy objectives and the role that passenger mobility could play in supporting ambitions connected to environmental sustainability, road traffic congestion, land use, and densification policies, besides tighter public budgeting. These developments came in conjunction with reforming dynamics that may already have been present in those countries, for example, due to decentralization policies and budgetary problems. Furthermore, they were propelled by a mixture of impulses from economic theory and concrete reform experiences. Influential economic theories where in particular the theory of contestable markets (Baumol, 1982) and a renewed interest for competitive tendering (franchise bidding) as a regulatory mechanism for monopoly operations (Demsetz, 1968). Important experiences had been present in different countries and involving different modes of transport. The United States and the British long-distance coach sector were deregulated since 1980, followed by Sweden and Norway. Deregulation also spread to the local and regional bus sector outside London in 1986 with some clear influence from contestability theory. In parallel, further reform experiences based on the usage of competitive tendering grew in the bus sector in London (1984) and later in Denmark (Copenhagen in 1991), Sweden (1989), France (reform of contracting in 1981 and stricter tendering rules in 1994) and the Netherlands (2001). In the railway sector, in 1987 Japan implemented privatization reforms combined with yardstick competition and price regulation, while the United States, since 1980, opted for a far-reaching deregulation in rail freight. The British Government, rather than deregulating, introduced competitive tendering in the railway sector (known as railway "franchising") in 1994.

What Reforms: Deregulation, Liberalization, and Privatization

The regulatory reforms in PT that have appeared during the last few decades usually combine deregulation, liberalization, and/or privatization. Deregulation is characterized here by the process of reducing the number of rules to which transport operators are subject to in the market in which they operate, resulting thus in an enhanced behavioral freedom in terms of the determination of service production and characteristics. Liberalization, in turn, is defined here as the process allowing other operators, in addition to the incumbent, to get access to the market, whatever the degree of behavioral freedom allowed by regulation to operators on that market. Finally, privatization here corresponds to the process of transferring the ownership of a company or agency from the public sector (such as the national or a local government) to the private sector. It is important to note that the extent to which deregulation, liberalization, and privatization are present can substantially differ according to the reform option chosen and the preexisting organizational form and institutional configuration of the sector. Regardless of the degree of deregulation, liberalization, and privatization used, a common characteristic of most—though not all—reforms that have been implemented during the last decades is the recourse to some elements of competitive pressure or the modification of already existing competitive arrangements. The way to organize such competition, however, varied substantially across and within countries and cities.

Two main classifications help understand changes that occurred in the last decades. First, a dichotomy needs to be established to distinguish PT systems based on free market competition and systems based on competitive tendering of monopoly rights by a transport authority. Second, the main policy options for reforms within these two types of systems can be grouped into four basic models: deregulated open market, competitive tendering, competitive regulation, and public sector reform. These two classifications are detailed in the next section.

How Do Reforms Work: Typologies and Basic Policy Pathways

Two fundamentally different categories of organization of the supply of PT services can be distinguished based on market entry rules; those defining the actors that have the right to initiate PT services. In market-initiated regimes, the supply of transport services is based upon the principle of autonomous market entry. In authority initiated regimes instead, transport authorities have the legal monopoly of initiative, it being the prerogative of the authority to produce or request the production of services (Van de Velde, 1999). Regimes based on market initiative can vary from full "open entry" to more-or-less strictly regulated "authorization regimes" (the latter were often dominated by publicly owned companies, in particular after the 1960s, while being historically based on private market initiative). Regimes based on authority initiative, in turn, can vary from "public monopoly" regimes to full "private concessions" awarded by the public sector. As to the former, one can distinguish further between public management of the operations and delegated management where the assets (vehicles, garages, tunnels, etc.) are publicly owned and made available to an operator to whom the management of the services is delegated after a specific selection and awarding procedure. In principle, all of these modes of organization can make use of further subcontracting of (parts of) the operations to third operators selected, for

Table 1 Categorization of reforms

	<i>Direct competition between operators: Operators face direct competition from other operators</i>	<i>No direct competition between operators: Operators are not directly threatened by other operators</i>
<i>Regimes based on market initiative:</i> Operators are, in principle, free to take initiatives to provide services	<i>Market deregulation:</i> The possibility for direct and 'daily' competition between operators is introduced	<i>Competitive regulation of monopolistic operators:</i> Historic operators (public or private) are regulated on the basis of a mutual comparison of their performances (such as yardstick competition)
<i>Regimes based upon authority initiative:</i> A transport authority organizes transport services and/or assigns a temporary right to an operator	<i>Competitive tendering of operational rights:</i> Periodic competition between operators for temporary operational rights is introduced	<i>Public operator governance reform:</i> The governance of the publicly owned operator is reformed to instill new performance incentives

example, by competitive tendering. Furthermore, it should be clear that real world examples often combine different elements of these alternatives and that several regimes can coexist within one area.

An essential aspect of this distinction is that in free market regimes, whether regulated or not, in principle any entrepreneur can initiate new transport services. In regimes based on monopoly regulation this is not case, regardless if PT services are to be provided by public sector operators or through a contractual delegation of a temporary right to independent operators via competitive tendering. In authority-initiated regimes, entrepreneurial rights are concentrated in the hands of the authority and only partially in the hands of the selected operator(s), and only to the extent to which the contract gives the operator(s) some leeway in service definition.

Choices across these alternatives determine the functioning of the sector in the longer run. Changes to such core elements usually require new or revised legislation. This makes them infrequent. In other words, only significant policy reforms generate a fundamental institutional reengineering of the sector. On the other hand, decisions pertaining to the functioning and fine-tuning of regimes are less likely to be anchored in legislation and are therefore more likely to be amendable in the medium to short term. This flexibility results in the existence of very context-dependent arrangements in different PT contexts.

Reform pathways followed in PT worldwide since the 1980s can be grouped in four main reform options: market deregulation, introduction of competitive tendering, regulatory reform of monopolistic operators on the basis of indirect competition, and public operator governance reform (Van de Velde, 2016). To be sure, real world cases rarely fit perfectly in this classification, hybrid reform packages can frequently be observed for different market segments. This section discusses these four main alternatives, also depicted in Table 1, and provides some implementation examples.

Deregulation

Where true “deregulation” was introduced in PT markets, it usually included all three elements defined above: privatization of the preexisting companies owned by the authorities, liberalization of the market by allowing the entry of new operators, and a deregulation of market behavior giving the operators a larger degree of freedom in the determination of their transport services. This is the case, for instance, of the deregulation of the local bus market in Great Britain outside London implemented in 1986 and adjusted by subsequent reregulations in 2000, 2008, and 2017. Other examples include the deregulation of the long-distance coach market in Great Britain in 1980, and local and regional bus transport in New Zealand in 1989. Whilst deregulated, these systems still involve some degree of intervention by the authority. This may include safety and environmental regulation and further “rules-of-the-game” that are meant to enhance the free market outcome (such as integrated ticketing, fares coordination, or participation in integrated information systems). Further rules can add entry selection based on an evaluation of the “desirability” of the entry by a regulatory function (a civil servant or committee), as was the case in many regimes in Europe between the 1930s and the 1980s. The coach sector in Europe is another example; most countries that have allowed the long-distance coach market to develop have chosen for a regime based upon market initiative with a large degree of deregulation, mainly removing normative barriers to head-on competition on the same route and simplifying the authorization process (Beria et al., 2018).

Competitive Tendering

The introduction of competitive tendering usually involves a process of liberalization allowing new operators, both public and private, to compete in formal tendering procedures. This may also involve incumbent players. The contracts awarded in these procedures can be referred to as “service contracts,” “concessions,” or “franchises,” depending upon the legal regime in place and their characteristics in terms of risk allocation. The gist of such arrangement is that it entitles the operator to a temporary right to operate services defined in the arrangement. This right can be more or less exclusive and vary in geographical scope (a specific route

or a delimited concession area, for example). Whilst many forms of competition are allowed in Europe, the EU Regulation 1370/2007 (and later amendments) gives the framework and clearly shows a preference for the awarding of exclusive rights by competitive tendering (Van de Velde, 2008), whereas in the United States, at least so far, contracting as a whole has not become a widespread option (TransitCenter and Eno Center for Transportation, 2017).

Contracts awarded in competitive tendering procedures may vary substantially in the way they allocate service design tasks between authority and operators. In some cases, authorities employ very detailed contracts that specify tightly the services to be provided, restricting the space operators could have to propose service innovation, thus restricting their focus to the production processes and actions that increase cost-efficiency. Such contracts tend to be small in size (one or a few bus routes) and are mostly gross-cost contracts, that is, contracts where the operator carries the production cost risk but not the revenue risk, which is borne by the transport authority. This is what happens in London, Copenhagen, and Helsinki for instance. In other situations, authorities may opt to allow greater room for operators to introduce innovation in service design. Examples can be found in the most Dutch provinces and many French urban public transport contracts. In these cases, contracts tend to cover a larger territory (e.g., a town or province) and are more often net-cost contracts, i.e. the operator carries both the production and the revenue risk. It is still the authority, however, who decides which geographic area and broad markets will be serviced, as well as the core characteristics of the services to be provided (all specified in the tendering documents).

The design of gross-cost and net-cost contracts and the associated allocation of risks and responsibilities across stakeholders has become increasingly nuanced and sophisticated over time. Public private partnerships and joint-venture agreements, for example, have been gaining traction in the sector as schemes not only to offer PT services, but also to design, finance, and implement the necessary infrastructure (Pulido and Hirschhorn, 2015).

Competitive Regulation

Competitive regulation refers to situations in competition is used in the regulatory context rather than “in” or “for” the market. With yardstick competition (Shleifer, 1985) for instance, payments from the authority to operators are based on a benchmark estimated considering the cost performance of a larger set of companies. In such arrangements, regulators regulate several services in contiguous spatial markets, comparing or “benchmarking” multiple firms as a way to overcome the informational disadvantage of the regulator. Thus, an important challenge in using yardstick competition is the need of comparable data, which is scarce in the transport sector. This may be one of the reasons for the rare use of yardstick competition compared to other options. Furthermore, even when data is available, another difficulty in using yardstick competition is that regulators should always take into account variation of costs across companies that are due to legitimate differences among them (in PT this could be different route types, congestion levels, peak demand characteristics, and other exogenous influences on costs) (Estache and Gómez-Lobo, 2005). Yardstick competition, when introduced, is likely to be a light deregulation or reregulation of the sector, perhaps combined with privatization but not necessarily involving liberalization other than through the possibilities created by the privatization. Since 1987, the Japanese railway sector is submitted to, among other regulatory regimes, yardstick competition. The aim behind the system is to push the less efficient rail companies in the yardstick group to improve their efficiency (Mizutani et al., 2009).

One further indirect form of competitive regulation can take place via the “threat,” by authorities, to introduce competitive tendering if incumbent operators do not perform according to—or sufficiently evolve towards—set benchmarks. Such target level could itself be set by the measurement of the outcome of a more competitive form of regulation in other areas, typically competitive tendering. This option has, for example, been used in a few cases in the Netherlands and Switzerland.

Reform of the Public Sector

Reforming the governance of a public operator is another widespread reform option. Reregulation and light deregulation are perhaps better descriptions of this pathway, as it often involves contractual, more functional and less detailed operational guidance to operators. There is no direct competitive threat in this option, but the threat of shifting to competitive tendering can constitute a power-play element during contractual negotiations—such was the case in Amsterdam. Some benchmarking elements can be used too, to determine broad reform targets in terms of demanded efficiency gains. Liberalization, however, is not part of this reform as it is based on keeping the public monopoly in place. Neither is privatization although the transformation of a branch of a public administration into a company structure (corporatization) is a common element of such reform.

Outlook: The Future of Regulatory Reforms and Competition in Public Transport

There is no simple answer to the question of whether reforms in public administration since the 1980s have been a success. The whole body of ideals that constitute the NPM has been severely questioned, and there is a generalized perception that these reforms led to fragmentation in policy design and implementation, resulting in the delivery of lower quality public services. As such, many policy areas and administrative structures have seen a change in emphasis away from structural devolution, disaggregation, and single-purpose organizations and toward a “joined-up government” or “whole-of-government” approach, that sought to apply a more holistic strategy in government (Christensen, 2012). In the PT sector in particular, results of policy reforms are indeed mixed. In some cases, they produced a number of positive effects, such as lowered costs per bus kilometer, increased bus kilometers, and

eventually some reduction in public subsidies. However, other analyses indicate that PT also suffered with increased fare levels or lower quality of services and decline in passenger levels (e.g., Preston and Almutairi, 2013; Veeneman, 2016). All in all, it remains difficult to disentangle the effects of the reforms per se, of public budget reductions that may have occurred, and of other local economic effects. Nonetheless, some agreement exists that in view of the fragmentation in policy design and implementation, greater policy integration (both across PT policies and between PT and other areas such as land use planning), ticketing and fare integration, as well as physical and modal integration in PT delivery, is essential to remediate the negative effects of neoliberal policies (Hirschhorn et al., 2018; Hull, 2005).

The upshot is that there is probably no right or wrong approach in the regulation of PT. The use of competition or not, as well as the way to do it, are characteristics that, on their own, are insufficient to ensure that the sector performs successfully. Developments over the last decades suggest that the option between the alternative policy pathways described above increasingly becomes an option of how to develop a hybrid model, smartly combining those elements of different models that are most suitable for local and regional contexts, considering the institutional history, the skillset of authorities and civil servants, and prevailing public values.

Nevertheless, this scenario of gradual evolution and relative dynamic stability in the institutional environment of PT seems to be on the verge of a new period of profound changes. Many authors observe macro behavioral trends and technological developments that promise to disrupt the existing institutional framework of the PT sector: broad concerns with the climate crisis, younger generations less interested in owning cars, increased opportunities for tele-working, the uncertain promise of autonomous vehicles, and smartphone mobility apps are just a few examples of factors transforming how the experience of travelling and even the need for it is seen, consequently affecting mainstream PT regulation (Buehler, 2018; Mulley et al., 2018). A common characteristic of innovations in PT technologies and services is that they result from a multitude of commercial initiatives that increasingly leaves PT institutional frameworks based on authority-initiative as a shrinking island in a growing sea of market initiative. This suggests that free market initiative may play an even more revolutionary role in the future of PT than competitive tendering has played over the past decades (Van de Velde, 2019).

The next challenge for the future of regulatory reforms and competition in PT lies on the acknowledgment by policymakers and planning authorities of the growing need to develop policy tools, strategies, and human skills to govern the nascent transition in the mobility sector (Hirschhorn et al., 2019). This will require public sector actors to lead and manage networks including a potentially growing number of public and private players interacting in an increasingly complex sector, made up of interdependent elements of varied nature, such as technology, infrastructure, and values. This may demand a more flexible approach to how PT is governed, potentially requiring new governance strategies beyond traditional forms of command and control, combining these existing practices with new ones that seek collaboration with a more diverse set of actors, with various backgrounds and new and competing ideas (Hirschhorn et al., 2019). This also means that the development of a new skillset by policymakers and authorities to cleverly using existing regulatory instruments is perhaps more at the core of the evolution of PT governance than new managerial models, increased funding and cost cuts.

Public Intervention in the Financing of Transport Infrastructures

Transport infrastructures have been fallaciously viewed as being public goods, that is nonrival and nonexcludable. With a nonrival good, one person's consumption of the service (e.g., driving miles on the highway) does not reduce the quantity that can be consumed by any other person (e.g., all other drivers can still drive as far as they want on the highway). This is the case with transportation infrastructure when congestion does not occur. A service is nonexcludable if, once produced, is accessible to all consumers; no one can be excluded from consuming such a service after it is produced (e.g., any driver can drive on the highway). However, this is not necessarily the case with transport infrastructures—typical exclusion mechanisms include toll roads or congestion pricing. For these reasons, transport infrastructures may be better conceived as club goods at least until reaching a point where congestion occurs (sometimes also called *artificially scarce goods*).

While nonexcludability and nonrivalry of pure public goods call for public sector intervention in the financing—in order to prevent the relevant form of good from being under-supplied^a—excludability and nonrivalry of goods call for public sector intervention in the regulation of access pricing, as financing of the good relies on revenues from use. In this context, why we do observe public intervention in the financing of transport infrastructure is mainly based on three arguments:

Efficiency: when the market includes failures (externalities, natural monopoly and imperfection of capital markets), the market price may not reflect the social value of the service, and the market may therefore not maximize total surplus—that is, the equilibrium may be economically inefficient.

Equity: transport infrastructure can be classified as services of general economic interest (SGEI), which are economic activities that public authorities identify as being of particular importance to citizens and that would not be supplied (or would be supplied under different conditions) in some circumstances, if there were no public intervention, for example, the case of *weak-demand areas*.

Stabilization policy: stimulus packages often highlight the important role of infrastructure investment in boosting the economy. Public infrastructure investment tends to enhance the productivity of the private sector and is thus likely to promote economic prosperity in normal times, while often offsetting falling private demand and stimulating the economy during recessions.

The implementation of an optimal public intervention can be limited by asymmetric information or incomplete contracting problems. Two problems may inhibit efficient contracting. The first is *adverse selection*, which in the context of procurement means that the contractor (the concessionaire or the agent) has better information than the owner (the contracting public sector, the principal) about the cost to complete the project. The second is *moral hazard*, which means that the contractor can take unobserved actions, such as shirking on quality, that may result in an inferior service; and the contracting public sector bears the relating risk.^b

^aTo finance an efficient level of output for a public good consumers must jointly agree that everyone contributes an amount equal to his own willingness to pay. However, since the provision of a public good is nonexclusive, everyone benefits once the public service is provided. Consequently, individuals have no incentive to pay as much as the service is really worth to them. They can behave as a free rider, paying nothing for a service while anticipating that others will contribute, which can preclude production by the private sector as no consumer would pay for it.

^bWith the standard adverse selection and moral hazard components, the principal should offer a menu of incentive contracts from which the project firm (agent) will select a contract that reveals its hidden information. In reality, such menus are not observed.

Externalities

An externality arises when the actions of any decision maker affect the benefits of other consumers or production costs of other firms in the market in ways other than through changes in prices. An externality that reduces the well-being of others is a negative externality. An externality that brings benefit to others is a positive externality.

The development of transport infrastructures may generate positive externalities on the economy (stimulation of the economic growth, increase in productivity and profitability) but can also impose internal and external costs. Internal costs (i.e., the price of driving) include gas and oil, wear and tear on the car, and any tolls, as well as the cost of time spent driving (the driver could have spent that time doing something productive). These are the costs a driver is likely to take into account when deciding whether to drive, but there are other costs (external costs, i.e., negative externalities) that she is much less likely to consider because she does not bear them herself—for instance, adding to traffic congestion and thereby increasing the travel time (and associated cost) for other drivers. The costs that a driver imposes on society include both these kinds of costs.

Other examples of negative externalities include environmental effects, noise annoyance, and accidents.

When externalities arise, the project's social returns can exceed its private returns and the classic efficiency argument for optimal regulation applies, closing the gap between private and social benefits and preventing the relevant form of infrastructure from being under-supplied.

Natural Monopoly and Infrastructure Financing with Economies and Diseconomies of Scale: Marginal Cost Versus Average Cost Coverage

A market is a natural monopoly if, for any relevant level of industry output, the total cost a single firm producing that output would incur is less than the combined total cost that two or more firms would incur, if they divided that output among them. That is, the cost function of a firm in the industry is *subadditive*.^c

Fig. 1 shows a natural monopoly market. The inverse market demand curve is D , and each firm has access to a technology that generates a long-run^d average cost curve $AC(q)$. For any output less than q_s units per year, a single firm can produce output more cheaply than two or more firms could (i.e., assume that the cost function of a firm is subadditive up to q_s). Note that, in Fig. 1, some levels of output along the demand curve can be produced more cheaply by two firms than one (e.g., $q = \tilde{q}$). However, such output levels would be demanded only at prices less than the minimum level of average cost. Thus, they would not be profitable. At all relevant levels of market demand, that is, all levels of market demand that could be profitably produced—the total cost of

Figure 1 Marginal vs average cost coverage under economies and diseconomies of scale.

^c Following alternative definition in literature, an industry has been called a natural monopoly, if a single firm producer can find price-output combination that preclude profitable entry by others (i.e., *sustainable price-output combination*). The existence of fixed costs of sufficient magnitude generally guarantee the existence of sustainable price-output combination for a monopolist, that is, making him invulnerable against entry (Baumol and Willig, 1981)

^d Consider "the long run" to refer to a period of time sufficient for all current commitments to be liquidated. Fixed costs are those costs that are not reduced, even in the long run, by decreases in output as long as production is not discontinued altogether. But they can be eliminated in the long run by total cessation of production. Sunk costs are those costs that (in some short or intermediate run) cannot be eliminated, even by total cessation of production, that is, in the long run all sunk costs are zero. As such, once committed, sunk costs are no longer a portion of the opportunity cost of production. Fixed costs do not necessarily constitute barriers to entry; that is, they need not have undesirable welfare consequences. Sunk costs do, however, constitute barriers to entry, where an entry barrier is anything that requires an expenditure by a new entrant into an industry, but that imposes no equivalent cost upon an incumbent, and as such does reduce the sum of consumers' and producers' surplus. It follows that phenomena such as fixed costs and scale economies need not do so.

production is minimized when one firm serves the entire market. Then, whether a market is a natural monopoly depends not only on technological conditions (the shape of the AC curve) but also on demand conditions. A market might be a natural monopoly when demand is low but not when demand is high.

A sufficient condition for cost subadditivity is the existence of fixed costs of sufficient magnitude. Then, a sufficient condition for natural monopoly is that the average cost curve must decrease with output over some range. That is, natural monopoly markets might involve economies of scale.

Transport infrastructures can be interpreted as a limiting case of a fixed cost relationship. Nonrivalry implies the *supply-jointness* or *nondepletable* condition, that is, at least over a substantial range, once the good is supplied to anyone, the cost of making its benefits available to additional people is relatively small (or zero). This is because transport infrastructures are typically a class of goods whose production has a large fixed cost component and for which there is a comparatively low marginal cost (in the sense of the cost of serving another customer).

If the bulk of the total cost is fixed, the sale of the good at a price equal to its marginal cost will incur a loss. Suppose $\hat{q}$ is produced and sold within the market, with technology $C(q)$ involving economies of scale, $MC(\hat{q}) < AC(\hat{q})$, that is, $\hat{q} < q_{MES}$. The Pareto outcome ensuring allocative efficiency, that is, marginal cost pricing $p(\hat{q}) = MC(\hat{q})$, would lead the monopolist to incur a loss equal to $\pi = p(\hat{q})\hat{q} - C(\hat{q}) = MC(\hat{q})\hat{q} - AC(\hat{q})\hat{q} = \hat{q}(MC(\hat{q}) - AC(\hat{q})) < 0$ (dark-shaded area in Fig. 1). In this case, first best intervention implies subsidization of the public good production and how large must the subsidy be to lead the market to produce the efficient level of output depends on the magnitude of the loss incurred by the provider of the infrastructure. Note that the Pareto outcome is efficient in a broader general equilibrium sense only, if we ignore the costs the government incurs to raise the funds to pay subsidies. General implementation problems include limited social and political acceptability of subsidies.

In order for the transport infrastructure provider with increasing returns to break-even it appears that the prices the monopolist charges for the services it provides will have to exceed marginal cost. One way to proceed in the single product context is simply to set a single price for each unit of the product equal to its average cost ($p(\hat{q}) = AC(\hat{q})$).^c This equilibrium price, which is equal to average total cost at the quantity that clears the market, is the second-best efficient uniform price when the firm is subject to a break-even constraint. Suppose $\hat{q}$ is produced and sold within the market, with technology $C(q)$ being subadditive $\hat{q} < q_s$ and involving diseconomies of scale, $MC(\hat{q}) > AC(\hat{q})$, that is, $\hat{q} > q_{MES}$. The Pareto outcome ensuring allocative efficiency, that is, marginal cost pricing $p(\hat{q}) = MC(\hat{q})$, would lead the monopolist to incur a surplus equal to $\pi = p(\hat{q})\hat{q} - C(\hat{q}) = MC(\hat{q})\hat{q} - AC(\hat{q})\hat{q} = \hat{q}(MC(\hat{q}) - AC(\hat{q})) > 0$ (lighted-shaded area in Fig. 1).

Then, the marginal cost-pricing rule implies a deficit for the government in case of increasing returns to scale and a surplus in case of increasing returns to scale.

Public Finance Versus Private Finance

Infrastructure financing may rely on public finance, where the investment is financed by the contracting public sector (with an optimal mix of taxation or debt)^f, or private finance (be it through outside equity or debt), where the operator has full control over his access to the financial market on top of control over operations.

The viability of private finance depends on the availability of public capital for infrastructure, that is, the countries budget for infrastructure, as well as on its efficiency in comparison with the economics of financing the project with public funds.

Relying on private finance has two conflicting effects. On the one hand, it adds a new level of contracting, between the contractor and credit institutions, which can exacerbate moral hazard. On the other hand, private finance would imply two advantages:

- private capital ensures higher value for money and could bring the experience of external lenders into risk assessment. In other words, there is a willingness to pay for the infrastructure, which reduces the risk of an inefficient resource allocation. When private investors risk their own money, they will require decision making as being realistic, and do not rely on data from authorities or lobby organizations, generally too optimistic (Flyvbjerg, 2009);
- if risk allocation is right the private sector can build and operate infrastructure more efficiently.

In this regard, having full control of access to the financial market and operations could improve the more traditional way of procurement where the cost of investments is paid through taxation and investments are not supported by such a level of competence inside the public contracting sector.

The choice between public or private finance is resolved in favor of private finance when external lenders are competitive, so that the case is similar to a situation where the government itself was enjoying the external lenders' expertise to provide funds at a cheaper cost. When external lenders are specialized in infrastructure risk, they might have some market power. In such an environment, it is unlikely that the government can earn all benefits from the external lenders' expertise. There would be a trade-off between the

^c In the multiproduct case, the reader may refer to the Ramsey-Boiteux pricing problem.

^f For transport infrastructures, present expenditures will provide future benefits. When the initial outlay is large, taxpayers may not wish to assume the entire cost at once and may prefer to pay over the years as the services of the new facility are enjoyed. Musgrave's option of *pay-as-you-use* finance would apply. Using current year tax money is sometimes described as "*pay-as-you-go*" in contrast to using debt instruments called "*pay-as-you-use*" financing. When using bond financing, project beneficiaries will pay for its use. The alternative *pay-as-you-go* financing method reduces the likelihood that larger, expensive projects can be built within acceptable time periods and means that future beneficiaries will not have to pay for its construction (Levinson, 2001; 2005).

benefits of the lenders' expertise and the extra distortions that financial contracts might bring. Recourse to private finance can however improve the operator's incentives, if lenders bring their expertise in monitoring effort.

In practice, the use of private finance has also been made because it has allowed the public sector to finance the construction of infrastructure "off the balance sheet" and to accelerate delivery of projects.

Forms of Infrastructure Financing and the Public-Private Partnerships

The relationship between public authorities and private investors to build, operate, maintain, and finance transport infrastructures for public services is regulated by long-term contracts which may take the form of concession agreements, lease contracts, management contracts, and more generally public-private partnerships (PPPs, 3P or P3).

The structure used for any particular project mainly depends on:

- The functions (design, construction, financing, operation, and/or maintenance) the private sector party will perform and the risks it will assume. Common risks involved are:
 - Political risk, associated to payments received by the private sector from the contracting public sector.
 - Technical risk, associated to assets breakdown and construction.
 - Financing risk, such as foreign exchange rate risk and interest rate fluctuation, operational risk (e.g., change in the price of raw materials), demand risk (e.g., over-optimistic demand forecasts), cost-overrun risk.
- The degree of operational control the public agency wants to have over any aspect of the project.
- Whether the private sector party will own the project assets at any time during the term of the agreement. **Fig. 2** shows the extent of private sector participation depending on contract types and sources of financing.

PPP can be used to raise private money—or to increase efficiency in the building process. **Table 1** describes the scope of different PPPs models.

In the BOT (Build-Operate-Transfer) framework, the contracting public sector allows a private investor to design, build, finance and operate infrastructure assets over an extended period, that is, "the concession period" (generally up to 30–50 years).

The contracting public sector will monitor the realization of the infrastructure and specify public services' obligations, that is, public service constraints (pricing structure, safety, and environmental regulations). The private investor is left with control rights and responsibility over how to deliver the service while meeting the prespecified standards. So design, construction, and operational risk are generally substantially transferred to the private-sector party. In return, the private-sector party is paid by the public agency or from fees collected from the project's end users in order to recover all of his costs and a reasonable profit to pay the service of the debt and to provide dividends to the shareholders of the project company. Ownership of the infrastructure rests with the private company until the end of the concession. Then, all operating rights and maintenance responsibilities revert to the public sector, without any remuneration of the private entity involved.

Typically, the concessionaire creates a special purpose vehicle (SPV) entity which is capitalized through the financial contributions of the project sponsors. Because the SPV entity has only limited workforce, it generally subcontracts a third party to perform its obligations under the concession agreement.

Figure 2 The relationship between public authorities and private investors.

Table 1 PPP models: functions the private sector party will perform and asset ownership

Model 1

Build-own-operate (BOO), Build-develop-operate (BDO), Design-construct-manage-finance (DCMF), Design-build-finance-operate (DBFO)

The private sector designs, develops, operates and manages an assets with no obligation to transfer ownership to the contracting public sector at the end of the operating contract.

Model 2

Buy-build-operate (BBO), Lease-develop-operate (LDO), Wrap-around addition (WAA), Build-rent-own-transfer (BROT)

The private sector buys or leases an existing asset from the contracting public sector, invests in the asset and operates the assets, with no obligation to transfer ownership to the contracting public sector at the end of the operating contract.

Model 3

Build-operate-transfer (BOT), Build-own-operate-transfer (BOOT), Build-lease-operate-transfer (BLOT), Build-transfer-operate (BTO)

The private sector designs and build an assets, operates it and then transfer ownership to the contracting public sector at the end of the operating contract (or at some other pre-determined date). The private investor may subsequently rent or lease the asset from the contracting public sector.

The financing is based on the expected cash flows of the project and it is typically on a “nonrecourse” basis, that is, the lenders will have no financial recourse for repayment of their loans against the contracting public-sector entity. Recourse is limited to the project company, that is, its assets and contractual rights.

A BOO (Build-Operate-Own) framework is a variant of the BOT and the difference is that the ownership of the newly built facility will rest with the private party.

The DBFO (Design-Build-Finance-Operate) framework is very similar to BOT, with the exception that there is not actual transfer of the ownership at the end of the entire concession period.

Fig. 3 describes a the typical relations among contracting public sector, the SPV and capital providers.

In the LDO (Lease-Develop-Operate) framework, the public-sector entity retains ownership of the newly created infrastructure facility and receives payments in terms of a lease agreement with the private sector. The lessee finance development and oversees operation. Payments received by the private investor are used in order to recover all of his costs and a reasonable profit to pay the service of the debt and to provide dividends to the shareholders of the project company. This approach is mostly followed in the development of airport facilities.

Literature finds that PPPs deliver efficiency gains when a whole-life cost approach to the project yields significant cost savings and when risk is effectively transferred to the private operator (Engel et al., 2013). Transferring design, construction, and operating risks to the contractor provides incentives for keeping project costs down and efficiently providing the service. PPPs are more beneficial when:

- a better quality of the infrastructure can significantly reduces costs (including maintenance cost);
- infrastructure quality has a great impact on the quality of the service and service demand (and service quality is verifiable);
- demand for the service is stable and easy to forecast (demand risk is low or the firm can diversify risk).

This points to the suitability of PPPs in the transport sectors, where infrastructure quality is key and demand is relatively stable.

The Payment Structure

The payments the private-sector party receives for performing its obligations under the agreement may be structured several ways. Consider the case where a contractor is in charge of both building and operation. The contractor bears costs C (excluding quality-enhancing and operating efforts) and receives a transfer t from the contracting public sector. For services where users pay, the contractor also receives revenues R . Thus, the contractor's payoff is $\pi + t$, where profits π are equal to $R - C$, if users pay, and to $-C$ if users do not pay. The following scenarios could be generally observed (Iossa and Martimort, 2015):

- *Contractible profits.* The contractor's profit $\pi = R - C$ is observable and can be contracted upon. The firm receives t from the contracting public sector, where $t = \alpha - (1 - \beta)\pi$. Under this profit-sharing rule, the contractor obtains a net profit of: $\pi + t = \alpha + \beta\pi$. In the case $\beta = 0$ the contractor receives a fixed payment and has no particular incentives to raise profits. Instead, $\beta > 0$ holds when the contractor bears profit risk. In the extreme case where $\beta = 1$, all risks are transferred to the contractor. This scheme is typically used for transport projects where users pay for the service, for instance toll roads.
- *Contractible revenues.* The contractor's revenue R is observable and can be contracted upon. The firm receives t from the contracting public sector, where $t = \alpha - (1 - \beta)R$. Under this revenue-sharing rule, the contractor obtains a net profit of: $\pi + t = \alpha + \beta R - C$.
- *User fee PPPs.* Revenue-sharing schemes are often used also in transport projects. A payment mechanism solely based on user charges corresponds to $\alpha = 0$ and $\beta = 1$ so that $t = 0$ and $\pi + t = R - C$. The contractor keeps all revenues and bears all demand risk. To mitigate these risks, private sector parties may require the public agency to guarantee a certain level of use and make payments to the private sector party if such minimum amount is not achieved, or to include in the PPP agreement extension or renewal provisions to allow the private sector party sufficient time to recoup its investment and earn a return.

Figure 3 The structure of relations among contracting public sector, the SPV, and capital providers in PPPs.

- *Availability-based PPPs.* A payment mechanism based on availability only, corresponds instead to $\alpha > 0$ and $\beta = 0$, so that $t = \alpha$ and with $\pi + t = \alpha + R - C$. The contractor's reward is fixed and paid by the contracting public sector for making the service available to users. The public agency bears the demand risk under this structure because the amount it pays to the private sector party does not change even if the project is not used to the extent anticipated. On the other hand, the private-sector party should consider obtaining political risk insurance.
- *Shadow toll-based PPPs.* Typically used for transportation projects, shadow tolls are per vehicle amounts paid to the private sector party by the public agency and not the users of the facility ($\pi = -C$). For instance, this is used when it may not be feasible or not desired for the road to include toll facilities. It corresponds to the case where $\alpha = 0$ and $\beta = 2\gamma + 1$ so that $t = \gamma R$ and $\pi + t = \gamma R - C$, $\gamma > 0$, with γR being the total amount paid to the private sector party by the public agency. The more the road is used (i.e., higher γ), the higher the payments the public agency is required to pay to the private sector party. These payments can, therefore, impose a significant burden on the public agency's finances. To minimize this pressure, many agreements include a cap on the amount the public agency is required to pay. In this structure, the private sector party and the public sector share the demand risk.
- *Contractible costs.* The contractor's cost (excluding quality-enhancing and operating efforts) C is observable and can be contracted upon. The firm receives t from the contracting public sector, where $t = \alpha + (1 - \beta)C$. Under this cost-sharing rule, the contractor obtains a net profit of: $\pi + t = \alpha + R - \beta C$.
 - *Cost-plus contracts.* The case $\beta = 0$ corresponds to a cost-plus contract where the contractor is fully reimbursed for its own costs, that is, $\pi + t = \alpha + R$
 - *Fixed-price contracts.* The case $\beta = 1$ holds for a fixed price contract, where the contractor receives a fixed payment $t = \alpha$.

Public Ownership Versus Private Ownership

Some PPP models combine the design and operation phases, together with the private ownership of the activities for the entire duration of the contract. Traditional contracting, on the other hand, corresponds to the case in which the public contracting sector purchases an asset built by the private sector and delegates the operations to the private sector. Ownership is important to the extent that assets have a residual value at the end of the contract.

Ownership gives the owner the right to the market value of these assets and this residual value provides incentives to invest in the quality of the assets, depending on the specificity of the assets.

Consistent with the literature on incomplete contracts, the residual value of the assets cannot be specified *ex ante* in a contract, although it can be observed *ex post* and can be traded on that date. Literature finds that the hold up problem is less severe under the private ownership of the assets for the entire duration of the contract, compared to public ownership, if there is a positive externality between the building and the management phases and vice versa when the externality it is negative.⁸

Generally speaking, private ownership is optimal for infrastructures with a high-residual value.

Introduction	378
Congestion	378
Capacity Allocation	382
Competition	383
Concluding Comments	384
References	384

Introduction

A conventional definition of economics is the allocation of scarce resources according to the laws of supply and demand. Where a rail system is congested, capacity becomes a scarce resource. Allocation of this capacity according to the laws of supply and demand becomes a key policy issue, which in turn determines the amount of on-track competition that is permitted. We therefore consider the key terms of congestion, capacity allocation and competition in turn, before drawing some conclusions.

Congestion

A formal definition of congestion is elusive, with most dictionaries describing the condition as a state of overcrowding or blockage. According to [The Institution of Civil Engineers \(1989\)](#), *congestion is a condition that arises because more people wish to travel at a given time than the transportation system can accommodate: a simple case of demand exceeding supply*. Moving from people to vehicles, [Vuchic and Kikuchi \(1994\)](#) note that,

when vehicular volume on a transportation facility . . . exceeds the capacity of that facility, the result is a state of congestion.

These definitions apply to all transport infrastructure and modes, for which, as demand on a network link or at a node approaches or exceeds the available capacity, congestion occurs and delays tend to increase exponentially with demand. Theoretical and empirical examples of this relationship are shown below. The empirical data are based upon recorded levels of capacity utilization (i.e., the percentage of maximum theoretical capacity that is used) and congestion-related reactionary delay (CRRD) at a critical switch (i.e., set of points) at Peterborough railway station, on the East Coast Main Line between London and York in the UK. Here, reactionary, or secondary, delay is “knock-on” delay, caused by delays to other train services ([Figs. 1 and 2](#)).

In principle, congestion should not occur on self-contained, scheduled transport systems like railways (and some commentators are critical of the use of the term congestion as a cause of delays to services as a consequence of this). In other words, using the terminology of the OnTime project ([Franke et al., 2013](#)), timetables should be feasible (trains adhere to scheduled paths under normal operating conditions without delays or conflicts), robust (they can absorb day-to-day operational variations and maintain planned schedule throughout), and stable (they can recover from primary delays so that trains regain their scheduled paths). However, while planned train service (as opposed to actual passenger) demand on railways should not exceed the normally available system capacity, there are inevitably situations where operational disruptions occur and some congestion is inevitable. These include “supply-side” problems such as train failures, switch failures, damage to electrification equipment, bridge strikes by road vehicles, speed restrictions, etc. and also “demand-side” issues, such as variations in passenger demand, sometimes causing extended alighting and boarding times, and thus extended dwell times and consequent delays. As a result of such events, capacity (and hence supply) may be temporarily reduced, and exceeded by planned demand, thus causing congestion to occur.

Ideally, sufficient spare capacity should be available in a railway system to enable the absorption of and rapid recovery from the effects of routine, “normal” levels of disruption, although this redundancy comes at a cost. It is, however, difficult to maintain and provide spare capacity when demand is high and growing, and when the cost and difficulty of providing additional infrastructure are prohibitive.

The situation is complicated further in the railway sector by the fact that there is typically no unique definition or agreed upper limit of capacity (in contrast with other transport modes). This is because the potential capacity depends not only upon the technical characteristics of the infrastructure and the trains using it, but also upon how the capacity is used or consumed, that is the mixture and sequence of trains being operated, some of which may have very different stopping patterns and average speeds. Alternate fast and slow trains on the same tracks is particularly intensive in terms of capacity use and, in such circumstances, “flights” of trains of similar speed are often scheduled together. As already indicated such capacity utilization can be calculated for both nodes and links.

Figure 1 Theoretical relationship between capacity utilization and secondary delay.

Figure 2 Relationship between recorded capacity utilisation and secondary delay (based on 3-hour time slices).

However, the upper capacity limit also depends upon the required level of performance (i.e., punctuality and reliability of train services) for individual routes (which in turn are combinations of nodes and links).

The wider relationships and interdependencies between timetable stability (i.e., performance with respect to delays), capacity, train speeds and service mix are illustrated in Fig. 3, taken from UIC's 2004 leaflet 406, "Capacity" (page 3). The yellow and black lines can be considered fixed in length, with the result that adjusting one of the four parameters shown will also affect at least one of the others. For example: as the number of trains increase, stability reduces (and vice versa); as average speed increases, stability reduces (and vice versa); and as heterogeneity increases, the number of trains reduces (and vice versa).

Figure 3 Operational and performance interdependencies.

However, disruptive events (such as the supply- and demand-side examples above) inevitably occur, causing temporary reductions in capacity, and thus congestion. On busy railways, operating at or near capacity, even small initial, or primary, delays to individual trains can cause widespread (through both space and time) congestion and secondary, or reactionary, delays.

The allocation (absolute and relative, i.e., total and mix of types) of train paths and capacity has a major bearing on the likelihood of congestion occurring. The more capacity that is allocated and utilized/consumed, the greater the risk of congestion and the less the scope for service recovery from perturbation. These risk are particularly great at nodes—stations and junctions (Armstrong and Preston, 2017). Also, the greater the heterogeneity, that is the variation between the speeds and stopping patterns of the allocated paths, the more capacity that is utilized/consumed, and the greater the potential for congestion.

In addition to these “macro-level” factors affecting the potential for congestion (and, of course, general infrastructure and rolling stock quality and reliability), train service quality and performance (i.e., punctuality and reliability) can be affected by a range of more detailed, “micro-level” aspects of the timetable and responses to disruptive, congestion-causing events. These include:

- The allocation (size and distribution) of running and dwell time supplements to individual trains—these help to ensure that trains can operate as scheduled, even when affected by minor variations in day-to-day operating conditions
- The allocation of “buffer times” between successive train movements—even if there is spare capacity in the overall timetable, running individual train pairs at or near their minimum headway, or time separation, increases the risk of unplanned interactions between them, and thus delay and congestion
- Timetable complexity, including variations in train stopping patterns, joining and splitting of trains en route, and the allocation and “sharing” of rolling stock and train crew across multiple routes, thus increasing the risk of delays and congestion being transmitted across the network, rather than being self-contained, or “quarantined” within the section of the network initially affected
- The availability, quality and flexibility of contingency plans available to respond to service disruptions
- The availability of signallers experienced to respond to a potentially wide range of both minor service perturbations and more serious disruptions, including the implementation of contingency plans
- The availability of sufficient human resources and quality of communication to respond quickly and effectively “on the ground” when problems occur

Figs. 4 and 5 illustrate both the macro- and some of the microlevel timetable factors, showing contrasting degrees of train service heterogeneity and complexity. Fig. 4 shows a spreadsheet-based graph of trains on London Underground’s Victoria Line between Tottenham Hale and Highbury & Islington in the morning peak, with very high levels of service frequency and uniformity, corresponding to the yellow line in Fig. 3. Fig. 5, in contrast, shows a graph of train services on the South West Main Line between Southampton Central and Eastleigh in the pre-morning peak, with a mixture of fast and local/stopping passenger services (blue and green lines, respectively), freight (red line) and empty coaching stock (ECS; black lines) trains, with varying stopping patterns and speeds. This corresponds more closely to the black line in Fig. 3.

On a busy mixed traffic railway, carrying a combination of fast, longer-distance and stopping/local passenger services, possibly in conjunction with longer-distance, but relatively slow freight services, developing a conflict-free, commercially attractive timetable that meets the needs of all its users and operators, is a major challenge. The challenge includes the provision of attractive journey times and service frequencies between origin and destination station pairs, by direct train service and/or via interchange, and

Figure 4 Victoria line train graph: homogenous services.

Figure 5 Mixed traffic train graph: heterogeneous services.

achieving a balanced, near-optimal outcome can be time-consuming and difficult. Train planning was described in a recent edition of *Modern Railways* magazine as a "deliciously complex nine-dimensional problem." These nine dimensions are:

- The external environment, including funding, governance and service specification, but also users and pressure/advocacy groups
- The passenger and freight markets to be served, how best to meet and balance their differing respective needs, and, particularly, how to respond to demand growth in a capacity-constrained system

- The three dimensions of space-these include the locations of and distances between the origins and destinations of demand, the gradients between them (although modern rolling stock is less affected by these, and less heavy freight tends to be carried on the network, than was previously the case), and the constraints imposed upon operational flexibility by a track-based system (railways have been described as a “single-degree-of-freedom mode of transport”, and as “operating in one-dimensional space”)
- The dimension of time-the travel times (“start to stop”, “start to pass”, “pass to pass”, and “pass to stop”) between location pairs, and the minimum times between successive train movements, are the fundamental “building blocks” (and constraints) upon which the timetable is based
- Infrastructure and rolling stock constraints - these include numbers and layout of tracks, loading gauge and axle load, numbers and layout of station platforms, signaling capability, availability and type of electrification, and rolling stock capacity and capability
- Deliverability of the timetable, including crew scheduling and changeovers, capacity utilization, reliability and punctuality
- Commercial considerations, i.e. the business case for a planned timetable, the anticipated revenue and costs of operation, and the resulting profit or subsidy requirement.

It can thus be seen that railway timetable development and capacity allocation is a highly complex, multidimensional and multistakeholder, and time-consuming process, with considerable scope for problems and error, as witnessed in the case of the May 2018 timetable update in Britain, and the effects it had on users of Northern and Govia Thameslink Railway (GTR) train services in particular.

Capacity Allocation

Partly because of the complexity of producing safe and reliable timetables, railways have traditionally been vertically integrated monopolies, with one organization responsible for both train services and infrastructure. In such circumstances, train paths are allocated using an administrative system of centralized command and control. Where there are conflicts in timetabling, these are typically resolved based on an hierarchy of service priorities, loosely based on perceived willingness to pay. For example, a high value, regular express service will typically be given priority over a low value, irregular freight train as it is believed its customers have a higher willingness to pay to avoid delays. Such priorities are often enshrined in timetable planning rules and are also used for rescheduling services in the case of major delays rather than first come, first served approaches. Perfect planning would use variants of social cost-benefit analysis to determine these priorities. In the absence of such analysis, administrative methods only work well when all transactions are internalized within the one firm as when there are many firms there will be information asymmetries between the infrastructure authorities and railway undertakings. In practice, priority allocation methods tend to favor existing services and can be criticized as stifling innovation and enshrining grandfather's rights.

Where there is a fragmented industry structure, with vertical separation (infrastructure operations separated from train service operations) and/or horizontal separation (several train service operators competing with each other), then the traditional capacity allocation methods break-down. Such a fragmented structure is becoming the norm in the Europe Union following Directive 91/440, which encouraged vertical separation, at least of accounts, and the slow emergence of the Single European Rail Area. The initiatives in Europe followed on from the deregulation of railroads in the US as a result of the Staggers Act (1980). In such cases of market liberalization, given rail infrastructure is a natural monopoly, access and the concomitant prices (track access charges) need to be regulated by a third party, such as the Office of the Rail Regulator (and its successors) in the UK or the Interstate Commerce Commission (and its successors) in the US.

One approach is the efficient component pricing rule as championed by William Baumol and used in the United States (Baumol, 1983). Access is granted to an entrant if they are prepared to pay at least as much as the revenue foregone by the incumbent as a result of entry minus the amount the incumbent charges itself for the use of the infrastructure. Where additional paths are provided (rather than the incumbent is supplanted), the entrant should be charged the incremental costs of these paths and the opportunity cost (net revenue foregone) to the incumbent of providing these paths. However, this presupposes honest and transparent accounts and that incremental costs and revenues can be easily measured, which even for additional expenditure on track maintenance has not proved straightforward.

In Europe, there have been four packages of railway reforms. The First Railway Package originated in 2001 and made provisions for open access competition in the international rail freight market, initially on the Trans European Rail Freight Network. It included directives to ensure fair track access and charging. The Second Railway Package was outlined in 2004 and extended rail freight deregulation to the whole network (realized in 2007). It also included directives for the harmonization of safety requirements and certification, and for interoperability, as well as a regulation for the creation of a European Railway Agency (ERA - renamed the European Union Agency for Railways in 2016) for safety and interoperability. The Third Railway Package was approved in 2007 and includes the liberalization of international passenger services by 2010, the harmonization of train drivers' licences and the inclusion of passenger rights and freight service quality regulations. The Fourth Railway Package was approved in 2016 and aims to complete the single European railway market by permitting open access competition for domestic services, competitive tendering for public sector contracts and the harmonization of regulation through the ERA. In addition, framework conditions were established concerning the independence of infrastructure managers, access to stations and facilities, through ticketing and inter-available ticketing.

There is thus harmonization at the European level. For example, European Union Directive 34/2012 requires infrastructure managers to grant nondiscriminatory access to railway undertakings and follow set procedures for the allocation of railway infrastructure capacity and set methods for the calculation and collection of infrastructure charges. Nonetheless, there has been a wide range of rail infrastructure charges, with at one extreme those based on short run marginal cost, related mainly to maintenance (as in Sweden) and at the other those based on fully allocated average costs (as in France for High Speed services or in Central and Eastern Europe for freight services), although only rarely have congestion costs been internalized (Nash, 2005). Hybrids might involve a two-part tariff, where an entry fee makes a contribution to fixed costs (dependent on the amount of subsidy) and a usage fee covers variable costs or some form of Ramsey pricing in which inelastic markets face higher charges than elastic markets, with the mark-up dependent on the nature of the budget constraint.

Where capacity is scarce, marginal cost charging that takes into account congestion or scarcity costs is required, although such charges are not straightforward to calculate (Johnson and Nash, 2008). A congestion charge is the appropriate capacity cost where the train in question constitutes an additional train to what would otherwise have been run. Such charges have been levied in Britain since the first periodic review of access charges in 2000 and are based loosely on the exponential relationship between additional trains and delays, as shown by Figure 1 but are charged by service group and include a large amount of averaging.

Where the train in question runs instead of some other train, the appropriate capacity cost is the opportunity cost of trains forced off the system by lack of capacity. Such scarcity costs can be estimated as the sum of the additional amount of traffic attracted to rail by the presence of this potentially additional train multiplied by the price paid, the consumer surplus to rail users as a result of the additional quality and capacity provided by the train (including reduced crowding on other services) and the savings of external costs to road users and the public at large from the train attracting passengers from road. From this should be subtracted the train operating, infrastructure and external cost savings from failing to run this train. This might be seen as a social version of Baumol's efficient component pricing rule. The practical problem is to identify and quantify the appropriate alternative services.

Another approach is to identify sections of infrastructure where capacity is constrained and to charge the long run average incremental cost of expanding capacity (Hysten, 1998). However, this is a very difficult concept to measure as the cost of expanding capacity varies enormously according to the exact proposal considered and it is not easy to relate this to the number of paths created since they depend on the precise number and order of trains run. It may be argued, however, that more appropriate incentives are given to infrastructure managers if they are allowed to charge the costs of investment they actually undertake, rather than for the scarcity resulting from a lack of investment, at least if they are commercially oriented. Short run marginal cost pricing can encourage the infrastructure manager to restrict capacity in order to keep prices high, whereas a system where a capacity charge reflected actual expenditure on expanding capacity would overcome this problem.

In Sweden, in the context of initially a low density of service and hence some spare capacity, it appears that some 30 years of using short-run marginal costs has meant that the network has been filled with subsidized local services to the detriment of more commercial longer distance services. In Great Britain, where franchised passenger train operators face a two-part tariff but open access passenger and freight operators face only a variable charge, the regulator has permitted some open access entry using the not primarily abstractive test. In this test, entrants have to demonstrate that they are generating new demand and not just abstracting demand from existing services. This has limited entry to serving peripheral markets that have not traditionally been well served by the incumbent. There has though been a substantial increase in franchised train operations, possibly in part to block open access entry but also because promises of higher service levels increase the chances of franchise bids being successful. In neither Sweden nor Great Britain has there been substantial expansion of infrastructure capacity. Instead, intensity of utilization has increased, with some deterioration of performance.

Theoreticians have proposed that auctions would be the most appropriate way to allocate rail infrastructure (Brewer and Plott, 1996). However, this would require huge combinations of space (typically access should be allocated at the signal block level) and time that would be computationally prohibitive for a reasonable scale mixed traffic railway. Furthermore, complex interdependencies between paths (and the services using them) would need to be taken into account. Solutions might involve an iterative process in which operators initially put in separate bids for train paths, with some indication of the extent that they would be prepared to be flexible. These bids would then be optimized into bundles of paths that operators would be able to rebid for. This would mimic aspect of the existing administered timetabling process (Nilsson, 2002).

Competition

Given the above, it is perhaps not surprising that competition within railways has been relatively limited and vertically integrated systems remain the norm, either in private ownership (Class I railroads in the US or the three main passenger railways in Japan) or public ownership (for example China, India and Russia). Infrastructure is allocated using internal bureaucratic processes rather than external contractual mechanisms. In some respects, this lack of within rail competition may not matter where there is intermodal competition from air, road or sea, efficient practices will be promoted. Where there has been intramodal competition, for example in North West Europe and, to an extent, in Latin America, off the track competition, in the form of concessions, franchising and tendering, is more typical than on the track competition, with infrastructure again being allocated using administrative rather than market-based measures. Where there has been on track competition, this has partly been stimulated by relatively low track access charges (Austria, Czech Republic, Italy, Sweden). There have been concerns that such oligopolistic (small group) competition may lead to too much service being provided at too high a price compared to a welfare maximizing benchmark (Preston, 2008). The

recent evidence from Europe is that services have indeed increased on competed routes but prices have come down, at least in the short run, and there has been greater product differentiation (Beria et al., 2019; Laroche et al., 2019; Tomes et al., 2016). However, this is compared to a monopoly benchmark in which there may have been too little service at too high prices, whilst it is by no means certain that the intense on-track competition being seen in some European countries can be sustained financially by the protagonists in the long-term.

Concluding Comments

Given the high degree of technical interdependencies in railway systems, safe and reliable operations require a degree of redundancy. This means that congestion effects can begin to appear at relatively low capacity utilization levels. In the absence of appropriate charges, this poses a challenge for the allocation of train paths through the infrastructure. The traditional solution has been for the railways to be vertically integrated monoliths, with little or no competition and track access allocated using centralized administrative processes. However, this is a description of the analogue railway. The digital railway promises to change the nature of some of these interdependencies. Moving block signaling, such as European Train Control System Level 3, has the potential to increase capacity by 40%, at least on plain track (Wendler, 2007), thus reducing congestion and increasing the scope for competition. Smarter timetabling and dynamic rescheduling can reduce the occurrence and impact of delays. Advances in machine intelligence and high-performance computation mean that decentralized market-based allocations of track access, through auctions, are now a practical proposition. It remains to be seen if this new digital age will recast railway operations and economics, by moving to a more open system in which on-track competition becomes the norm. It is possible that such developments have, at least for now, been thwarted by the downturn in the demand for passenger railways in many parts of the world following the emergence of COVID19 in Spring 2020.

Introduction

Public Private Partnership (PPP) is a fuzzy expression, covering a lot of different but close meanings about the association of public and private funds for the realization of essential facilities. The corresponding procedures are widely used for almost all kinds of public investments but more so in transport sector where it is shaped by several interesting features, which we will delve into after discussing some basics of PPP.

What is a PPP?
